THE UNIVERSITY OF CALGARY
FACULTY OF GRADUATE STUDIES

The undersigned certify that they have read, and recommend to the Faculty of Graduate Studies for acceptance, a thesis entitled "Analysis of Eclipsing Binaries in the Globular Cluster M71" submitted by Jason Reed McVean in partial fulfillment of the requirements for the degree Master of Science.

Supervisor, Dr. E. F. Milone, Dept. of Physics and Astronomy

Dr. S. R. Sreenivasan, Physics and Astronomy

Dr. T. A. Clark, Physics and Astronomy

Dr. D. L. Rod, Mathematics and Statistics

94/09/23

Date

Abstract

The light curves of five eclipsing binary stars were analyzed using the University of Calgary's enhanced version of the Wilson-Devinney light curve modelling code and a simplex enhanced version of the same. Four of the binaries were found to be probable members of M71, while the fifth (V3) is less likely to be. Three of the probable members are contact binaries with contact parameters ranging from 0.06 to 0.27. The fourth probable member (V4) is a detached or semi-detached Algol-type system, the detached model being the more likely. The absolute parameters of all of the systems were calculated and the individual components were placed on the M71 colour magnitude diagram. The contact systems were used to check the recent colour-period-luminosity relationship for W UMa systems derived by Rucinski (1994). The possibility of mass exchange is discussed for V4 and it is concluded that mass exchange has probably not occurred.

Acknowledgements

I would like to thank Dr. L. Yan and Dr. M. Mateo for kindly supplying their light curves, without which, there would have been little to write about. Special thanks to my supervisor Dr. E. F. Milone for tirelessly correcting “bolemetric”, weeding colloquialisms, suggesting new ideas, burying me in relevant papers, sponsoring trips to exotic locations, and years of generous support. More thanks to my parents for helping out with all that last minute stuff.

1.0 INTRODUCTION

1.1 The unique astrophysical problem

The study of astrophysics suffers from a unique problem of scale. The size, distance and time scales of typical astrophysical phenomena render observation difficult and experimentation largely impossible. The limited data that can be collected from afar often lack crucial information that temporal variation would help supply, but little observable change can be expected in the vast majority of astrophysical structures in hundreds or thousands of years, so the sum of all modern astronomical observation essentially amounts to a single frame in the lifetime of the universe. As will be seen, the study of binary stars is one method of alleviating some of these problems.

A star's evolutionary path is traditionally thought to be determined primarily by its initial composition and mass, although other factors such as angular momentum are increasingly thought to be contributors as well. But without a doubt, the initial mass is the most important parameter. And yet, mass is also one of the most elusive characteristics of a star. This elusiveness is due, once again, to the problem of scale in astrophysics. If stars were not so far away, we could easily measure their mass once we arrived close enough to feel their gravitational pulls. Or alternatively, if events happened much more quickly, we could watch the path of a star among its comparatively close neighbors and deduce its mass from the interactions that take place.

Since mass is very important to a star's evolution, one expects its influence to be observable in many ways. Unfortunately, most of the means by which mass can be deduced rely on complicated processes. For instance, the gravitational acceleration felt by

atoms in a star's upper atmosphere has an observable effect. A more direct method of determining mass is through studying binary stars.

1.2 The importance of binary stars

Binary stars address the problem of mass determination because, by Newton's laws, they accelerate each other in a ratio proportional to the inverse of their masses. By virtue of the proximity of the two components, the time scale over which observation is necessary in order to see their interaction and hence deduce their masses is typically one of days or hours. Mass is not the only parameter that can be measured for binary stars. In fact, the study of binary stars is one of very few ways that many properties of stars can be determined in a direct fashion. Considering that roughly 50% of stars are in binary systems (Mihalas and Binney, 1981), if even a small fraction of binary stars yield their vital information, they act as a good sample of all the stars in the galaxy.

The amount of information that is extractable from the study of a binary star depends upon the type of binary star in question. Categorizing binaries according to how they are detected leads to three types: *visual*, *spectroscopic* and *eclipsing*.

A visual binary system consists of two gravitationally bound stars that can be individually resolved. The way in which the stars move around each other can be described by 8 orbital elements: the time of periastron passage, T ; the time between periastron passages, P ; the semimajor axis of the orbit, a ; the eccentricity of the orbit, e ; the position angle of the node, Ω ; the inclination of the orbit, i ; and the longitude of the periastron, ω . These orbital elements are illustrated and described in Figures 1a and 1b. Since the two stars can be resolved, it is possible to observe the period, P , and the projected orbits of the stars on the plane of the sky. The inclination, i , of the orbit can be

Figure 1a - The elliptical relative orbit of a binary system has the more massive star at its focus. The sum of the distances between any point on the ellipse and the two foci is equal to $2a$, where a is the semimajor axis of the ellipse, one of the elements necessary to describe a binary system orbit. The eccentricity e of the orbit, another orbital element, is equal to the ratio of the centre-to-focus distance and the semimajor axis. The semiminor axis b is measured perpendicular to the major axis from the centre O to the ellipse. The apastron is the point in the orbit at which the stars are at maximum separation. The periastron is the point of closest approach between the two stars. A third orbital element is the time of periastron passage T . The time between periastron passages is the fourth orbital element: the period P .

Figure 1b - The remaining elements necessary to describe a binary system orbit are illustrated. The position angle of whichever node is between zero and 180 degrees, measured eastward from north along the projected orbit, is designated Ω . The inclination i is the angle at which the plane of the true orbit tilts out of the plane of the sky. Finally, the longitude of the periastron ω is the angle between the line of nodes and the periastron p , measured along the true orbit.

deduced by measuring the apparent displacement of the more massive star from the focus of the less massive star's elliptical relative orbit. Once the inclination is known, the true orbits of the stars about the centre of mass of the system can be plotted. The mass ratio, q , of the components can then easily be found by the ratio of the distances, d_i , of the stars from the centre of mass:

$$\frac{d_1}{d_2} = \frac{m_2}{m_1} = q, \quad (1)$$

where m_1 and m_2 are the masses of the more massive star and less massive star respectively. The angular semimajor axis, a' , can also be directly observed, and can be converted to the semimajor axis, a , provided that the distance, D , is known using

$$a = a' [\text{radians}] \cdot D \quad (2)$$

Knowing the distance is not an entirely unreasonable presumption since the visual binary must be reasonably nearby for the components to be resolved and still have an observably short period and an orbit small enough to resist disruption from passing stars¹. The distances to nearby stars can be easily found by measuring their parallaxes using

$$d (\text{parsec}) = \frac{1}{p (\text{arcsec})}. \quad (3)$$

Once the semimajor axis is known, the total mass of the binary system can be calculated using Kepler's third law:

$$(m_1 + m_2) = \frac{4\pi^2}{GP^2} (a_1 + a_2)^3, \quad (4)$$

¹ Hills (1984) estimates that binaries with periods longer than 800 years would not survive star-star interactions in M71 but a stable system with an 800 year orbit would be very difficult to observe precisely due to incomplete coverage.

where a_1 and a_2 are the semimajor axes of the individual stars' orbits around the centre of mass such that

$$a = a_1 + a_2. \quad (5)$$

Together, the total mass and the mass ratio allow the calculation of the individual component masses.

Of course, the precision of the individual mass determinations is strongly dependent on the precision of the measurements made. This can be quite low for distant systems since earth-based observing is limited by atmospheric fluctuations to angular resolutions of at best ~ 0.5 arcseconds. The close proximity required to observe visual binaries combined with the potentially very low precision for the more distant systems limits their usefulness to studies of our local region of space.

A spectroscopic binary system is a system in which the motion of one or both components can be detected by periodic variations in the Doppler shift of the lines of the system's spectrum. The Doppler shift of a spectral feature is related to the star's radial velocity, v , by the equation:

$$v = \frac{\Delta\lambda}{\lambda} c, \quad (6)$$

where λ is the unshifted wavelength of the spectral feature, $\Delta\lambda$ is the Doppler shift in the feature's wavelength, and c is the speed of light. Plotting the star's radial velocity (RV) against time gives the *radial velocity curve* of the star (see Figure 2). Because RV curves are periodic, it is common to plot radial velocity against phase, ϕ , rather than time, t . The phase of an observation is calculated using:

$$\phi = \frac{t - E_0}{P} - \text{int}\left(\frac{t - E_0}{P}\right), \quad (7)$$

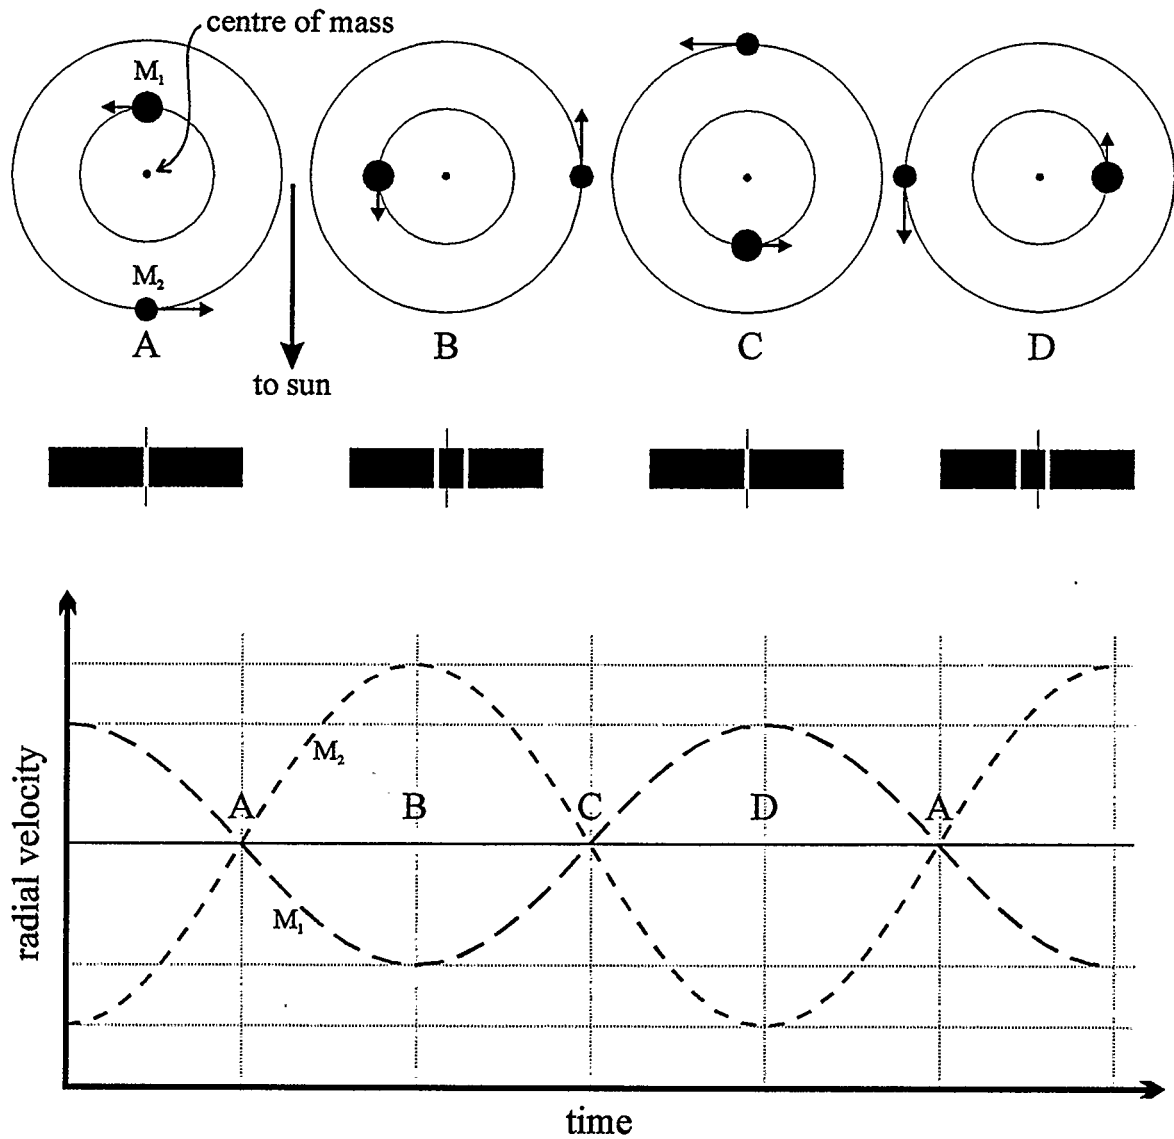

Figure 2 - A simplified radial velocity curve. The top of the figure shows the orbital configurations that correspond to the points A, B, C, and D in the radial velocity curve at the bottom of the figure. The middle portion illustrates the Doppler shifting of a spectral feature as the stars orbit.

where E_0 is the epoch of the system, a time that defines the zero-phase of the binary system. If one of the stars is considerably brighter than the other, it may not be possible to discern the second star's spectrum, in which case the system is a *single-line spectroscopic binary*. A *double-line spectroscopic binary* is one in which both stellar spectra are discernible, which is facilitated if the luminosities of the two stars are comparable and the spectral types are significantly different. This is because we depend on spectral lines to measure radial velocities, and distinct sets of lines moving in two separate groups aids in distinguishing the stars' contributions to the combined spectrum.

For a double-line spectroscopic binary the mass ratio of the components can be found from the ratio of the amplitudes of the radial velocity (RV) curves, V_i :

$$\frac{V_1}{V_2} = \frac{m_2}{m_1} = q. \quad (8)$$

The total mass can again be found using Kepler's third law if the semimajor axis is known. For circular orbits, the projected semimajor axis of the system's orbit can be found from the relative velocity—determined from the Doppler shift of the spectral lines—of one of stars and the period of the orbit using²:

² For a non-circular orbit, equation (9) becomes considerably more complicated for several reasons: the orbital velocity is not constant, so that an integration is required; the orbit is not circular, meaning the semimajor axis, a , is dependent on both the circumference, C , of the ellipse and its eccentricity, e , according to

$$a = \sqrt{\frac{C^2}{2\pi^2(2 - e^2)}};$$

and the relationship between the true semimajor axis and its tangential component, a_\perp , depends upon both the inclination i and the longitude of the periastron ω .

$$a_{\perp} = \frac{Pv_{\text{relative}}}{2\pi}, \quad (9)$$

where a_{\perp} is the projection of the semimajor axis onto a plane perpendicular to the plane of the sky:

$$a_{\perp} = a \cdot \sin i, \quad (10)$$

and

$$v_{\text{relative}} = |v_1| + |v_2|. \quad (11)$$

To find the true semimajor axis from the projected semimajor axis, again the inclination must be known. However, the inclination cannot be found from velocity curves alone; only the lower limit to the individual component masses of double-line spectroscopic binaries is determinable in general.

In the case of single-line spectroscopic binaries, the amplitude of only one velocity curve is observable so that considerably less information can be found. Combining equations (8), (9), (10) and (11) gives:

$$a \cdot \sin i = \frac{1}{2\pi} \left(\frac{m_1 + m_2}{m_2} \right) P v_1, \quad (12)$$

where v_1 is the observable radial velocity in the circular orbit case. Cubing this equation, combining it with equation (4) and manipulating the resulting equation gives

$$\frac{m_2^3 \sin^3 i}{(m_1 + m_2)^2} = \frac{P v_1^3}{2\pi G}. \quad (13)$$

The left hand side of this equation is the *mass function*, representing as much information as can be extracted from a single-line radial velocity curve. However, combined with the mass ratio, the mass function will allow the lower limit for the individual masses to be calculated, as was the case for a double-line spectroscopic binary.

The third type of binary star, the *eclipsing binary*, is a system in which the stars pass partially or totally in front of each other as viewed from earth as they orbit. This produces a periodic change in the brightness of the light from the system (see Figure 3). Plotting the brightness of the system against time gives the *light curve* of the eclipsing binary system. As is the case for RV curves, light curves are also often plotted using phase rather than time. The shape of a binary system's light curve is determined by the properties of the system, such as inclination of the orbit, temperatures of the stars, the size and shape of the stars, or the mass ratio, to name a few. For instance, W UMa-type binaries, which are characterized by continuously changing light levels and minima of similar depths, consist of two gravitationally distorted stars of nearly equal temperatures that are in contact or are nearly so. Algol-type binaries are characterized by light curves with nearly flat maxima and clearly delineated periods of eclipse. The stars of these systems are not in contact, although often one star is losing mass to its companion. Given all the factors that influence the shape of an eclipsing binary's light curve, there is potentially a great wealth of information to be found from studying eclipsing binary light curves (see Figures 4a through 4g for some samples). Among the parameters that are determinable is the inclination. To be an eclipsing binary star requires that the inclination be close to 90 degrees but a more precise determination of the inclination is possible by modelling the shape of the eclipses. The mass ratio can also be modelled, meaning that if a star is at once a spectroscopic binary and an eclipsing binary, individual masses, among other parameters, can be found. Other information such as size and physical dimensions, luminosity, temperature, and theoretically, even composition given a sufficiently high-quality light curve, can also be found.

However, some caution must be exercised before celebrating binary stars as a rich source of information. By definition, binary stars interact with each other. Therefore, it is

Figure 3 - A simplified light curve. When one star of an eclipsing binary system passes in front of the other as viewed from earth, the measured brightness of the system decreases. By modelling the shape of the light curve, information about the binary system can be found.

Figure 4a - The dependence of an eclipsing binary light curve on the orbital inclination is illustrated. The light curves were produced with the Wilson-Devinney light curve modeling code (see section 4.1) by varying i while holding all other parameters constant.

Figure 4b - The dependence of an eclipsing binary light curve on the temperature of the primary component is illustrated. The light curves were produced with the Wilson-Devinney light curve modeling code by varying T_1 while holding all other parameters constant.

Figure 4c - The dependence of an eclipsing binary light curve on the temperature of the secondary component is illustrated. The light curves were produced with the Wilson-Devinney light curve modeling code by varying T_2 while holding all other parameters constant.

Figure 4d - The dependence of an eclipsing binary light curve on the potential of the primary component (which controls its size and shape—see section 1.3) is illustrated. The light curves were produced with the Wilson-Devinney light curve modeling code by varying Ω_1 while holding all other parameters constant.

Figure 4e - The dependence of an eclipsing binary light curve on the potential of the secondary component is illustrated. The light curves were produced with the Wilson-Devinney light curve modeling code by varying Ω_2 while holding all other parameters constant.

Figure 4f - The dependence of an eclipsing binary light curve on the potential of a contact system is illustrated. The light curves were produced with the Wilson-Devinney light curve modeling code by varying Ω while holding all other parameters constant.

Figure 4g - The dependence of an eclipsing binary light curve on the mass ratio of the system is illustrated. The light curves were produced with the Wilson-Devinney light curve modeling code by varying q while holding all other parameters constant.

important to know how far this interaction extends. If it extends so far as to influence the evolution of each component, one cannot directly extrapolate the knowledge gained from the system to other systems. Perhaps the most obvious evolution-influencing interaction between binary components is mass exchange. Since mass is the most important property for the determination of the evolutionary course a star will take, it is reasonable to be concerned about evolutionary alteration through mass exchange.

1.3 Roche potentials and mass exchange

Mass exchange between binary components can result from a number of processes such as stellar wind and cataclysmic variation. Mass loss due to stellar wind can be quite significant for hot stars. Initially high mass stars (greater than approximately 60 solar masses) can lose all of their outer layers during main-sequence and early hydrogen-shell burning stages and expose their cores, preventing any evolution toward the red supergiant stage. Even less massive stars can be expected to lose quantities of mass significant enough to drastically alter their evolutionary paths (Chiosi & Maeder 1986). Huge quantities of mass can also obviously be lost due to cataclysmic variations such as novae or supernovae explosions. However, mass exchange resulting from Roche lobe filling is the most relevant to this discussion and will be described in more detail below.

Because of their rotation and mutual gravitational influence, binary components are not spherical, although sufficiently well separated stars may approach spherical shapes. The shape of the stars is defined by equipotential surfaces approximated by the equation

$$\Phi = -\frac{Gm_1}{(x^2 + y^2 + z^2)^{1/2}} - \frac{Gm_2}{((x-a)^2 + y^2 + z^2)^{1/2}} - \frac{1}{2}\omega^2 \left[\left(x - \frac{m_2 a}{m_1 + m_2} \right)^2 + y^2 \right] \quad (14)$$

(Kopal 1978), where x , y , and z are Cartesian coordinates centred on the more massive star (star 1), with the z -axis lying along the axis of rotation and the centre of star 2 lying at the coordinates $(a,0,0)$, and ω is the angular velocity

$$\omega = \frac{2\pi}{P} = \sqrt{\frac{G(m_1 + m_2)}{a^3}}. \quad (15)$$

Equation (14) assumes the orbit is circular, the stars rotate synchronously, and utilizes the Roche approximation, under which the mass of each star is centrally concentrated. These assumptions and approximations are quite reasonable in most cases. The first two terms are the gravitational components of the potential. The third term concerns the centrifugal flattening of the stars. By combining these equations and adopting m_1 as the unit of mass, a as the unit of distance, and the unit of time such that $G=1$, the potential Φ can be expressed in terms of spherical polar coordinates

$$\begin{aligned} x &= r \cos\phi \sin\theta = r\lambda, \\ y &= r \sin\phi \sin\theta = r\mu, \\ z &= r \cos\theta = r\nu, \end{aligned} \quad (16)$$

as

$$\Omega = \frac{1}{r} + q \left\{ \frac{1}{\sqrt{1 - 2\lambda r + r^2}} - \lambda r \right\} + \frac{q+1}{2} r^2 (1 - \nu^2), \quad (17)$$

where

$$\Omega \equiv -\frac{\alpha\Phi}{Gm_1} - \frac{m_2^2}{2m_1(m_1 + m_2)} \quad (18)$$

is the non-dimensional parameter used in the modelling software that was used for this work (see Chapter 4). Note that Ω should not be confused with Ω , one of the orbital elements of a binary system discussed above. This potential, generalized to account for nonsynchronous rotation and eccentric orbits, is given by Wilson (1979):

$$\Omega = \frac{1}{r} + q \left\{ \frac{1}{\sqrt{D^2 - 2\lambda r D + r^2}} - \frac{\lambda r}{D} \right\} + F^2 \frac{q+1}{2} r^2 (1 - v^2), \quad (19)$$

where D is the instantaneous centre-to-centre separation in semimajor axis units and F is the ratio of the angular rotation rate to the synchronous rotation rate. Note that D is phase dependent while F is constant for the system.

Equipotential surfaces are nearly spherical near the centres of the stars but become increasingly distorted as they get larger. The potential at which two cusped volumes that touch at the inner Lagrangian point L_1 are enclosed is called the first (or inner) critical potential. These volumes are the Roche lobes of the two stars. Beyond the first critical potential, the two surfaces merge into one dumbbell shaped surface. At the second (or outer) critical potential, a cusp is formed at the outer Lagrangian point L_2 . These Lagrangian points, as well as L_3 , represent points at which the slope of the potential is zero:

$$\frac{\partial \Phi}{\partial x} = 0; \quad y = z = 0. \quad (20)$$

As a star evolves and expands³ it will fill successively larger equipotential surfaces until its Roche lobe is filled, at which point material will spill through the inner Lagrangian point into the Roche lobe of its companion. The exchange of mass that takes place can be of such a magnitude that the more evolved star can end up as the less massive of the pair.

³ The expansion of the stellar envelope is due to an imbalance between the outward pushing radiation and gas pressure and the inward pulling gravitational force. The imbalance is due to an increase in core luminosity (and hence radiation pressure felt by the envelope) or shell luminosity in the case of stars undergoing shell burning. The increase can be due to the ignition of a new fuel or increasing core or shell temperature due to contraction when a fuel has been exhausted.

When one star overflows its Roche lobe, the system is a *semi-detached binary*. When both stars overflow their Roche lobes, the system is a *contact binary*. The envelopes of the stars then merge into a common, dumbbell-shaped envelope that can continue to expand up until its surface reaches the outer critical surface, at which point matter will leak through the outer Lagrangian point L_2 and be lost from the system. See Figures 5a through 5c for illustrations of detached, semi-detached, and contact systems.

The degree to which the stars fill their Roche lobes can be quantified with a *contact parameter* defined as

$$f = \frac{\Omega_{\text{inner}} - \Omega}{\Omega_{\text{inner}} - \Omega_{\text{outer}}}. \quad (21)$$

This parameter, sometimes referred to as the *fill-out factor*, indicates the degree of filling of the contact envelope. A value larger than one implies that the stars overflow the outer critical surface. A value of zero implies that the stars are barely in contact, as they just fill the inner critical surface. If the stars are not in contact, they do not have to be constrained by the same value of Ω and, hence, the two components will each have their own negative value for f .

Clearly it is important to know whether mass exchange or loss has taken place before drawing too many conclusions from the information gathered about a binary system. If the modelling results point to a semi-detached or contact system, then clearly evolutionary contamination has taken place, but even if the model describes a detached system, it remains possible that mass exchange could have occurred in the past. The probability of this can be estimated if the age of the system is known because, given the mass of the components, the approximate age at which evolution off the main-sequence occurs can be found from evolutionary models.

Figure 5a - The Roche lobe configurations of detached, semi-detached, and contact systems in the x-y plane. The less massive star is on the right. The inner critical surfaces (figure-8 shaped line) and outer critical surfaces (outer dumbbell) are shown with the surfaces of the components. In the detached system (top), both stars are smaller than the inner critical surface. In the semi-detached system (middle), one stellar surface is coincident with its Roche lobe. In the contact system (bottom), the components share a common surface that falls between the critical surfaces. These illustrations were produced with D. H. Bradstreet's *Binary Maker II*.

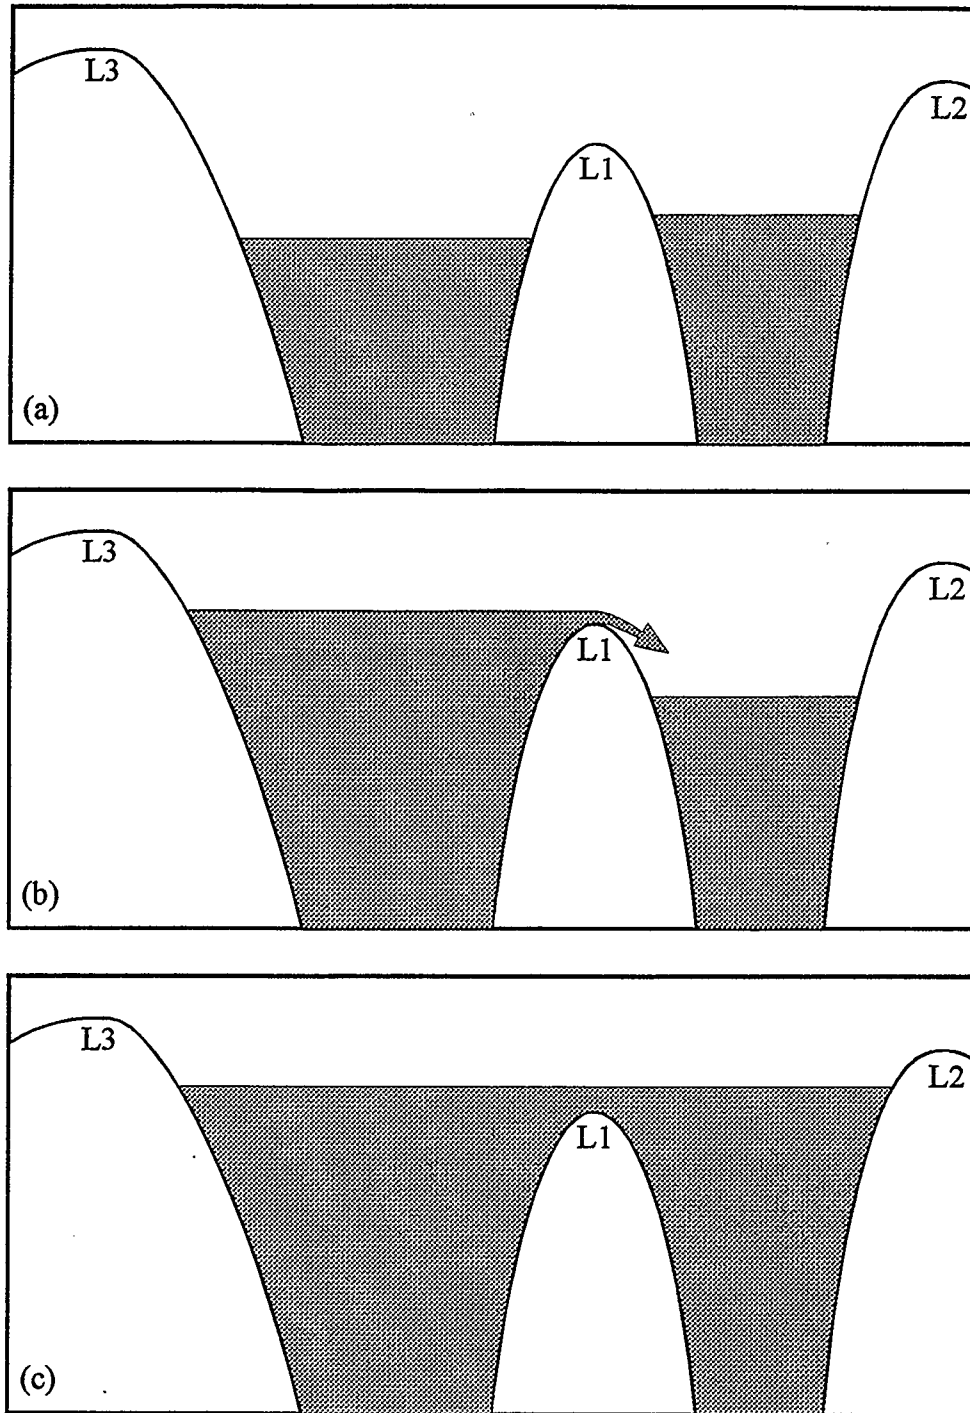

Figure 5b - The potential wells of a (a) detached system, (b) semi-detached system, and (c) contact system. In (a) there is no sharing of stellar material. In (b) the star on the left has expanded beyond its potential well and material spills into the potential well of the other star through the first Lagrangian point L1. In (c) both stars have expanded to a point that their now merged surface has a potential higher than that of L1. If they expand to a potential beyond L2, material will be lost from the system.

Figure 5c - Three-dimensional representations of detached, semi-detached, and contact systems (from top to bottom) produced with D. H. Bradstreet's *Binary Maker II*.

1.4 The importance of binary stars in clusters

If the binary star is a member of a cluster, then its age can be assumed to be the same as the age of the cluster, which can be estimated by fitting theoretical isochrones to the colour magnitude diagram (hereafter, CMD) of the cluster (see Figure 6 for an example of a CMD—that of the open cluster NGC 752 from Milone *et al.* (1994)). To avoid a circular argument, some caution should be exercised here, as it is ultimately these same isochrones that are to be tested using the binary system data. The size of a star of a given mass can also be plotted against age using theoretical models. With the age and mass of each binary component known, it is possible to determine if the stars have filled their Roche lobes in the past. Again, the same caution applies to this procedure. This should at least give an approximate probability of whether the binary's components have exchanged mass. If it is concluded that they have not exchanged mass, then one has a set of very important checks for the evolutionary models that are used to determine cluster ages because knowing the masses of two stars of known position on the CMD allows a direct comparison of observation and theory. For an example of this procedure, see Schiller & Milone 1988, in which the components of the detached system DS Andromedae are placed on the CMD of the open cluster NGC 752 (indicated with '+' symbols in Figure 6).

If the components have exchanged mass, then one still potentially has a system of well known current mass, age, temperature, luminosity, etc., which is important for studying the evolution of interacting binary stars.

These tests are necessary because the prevalence of use of evolutionary models is very great and yet there are very few tests that can be made of their accuracy. Given that

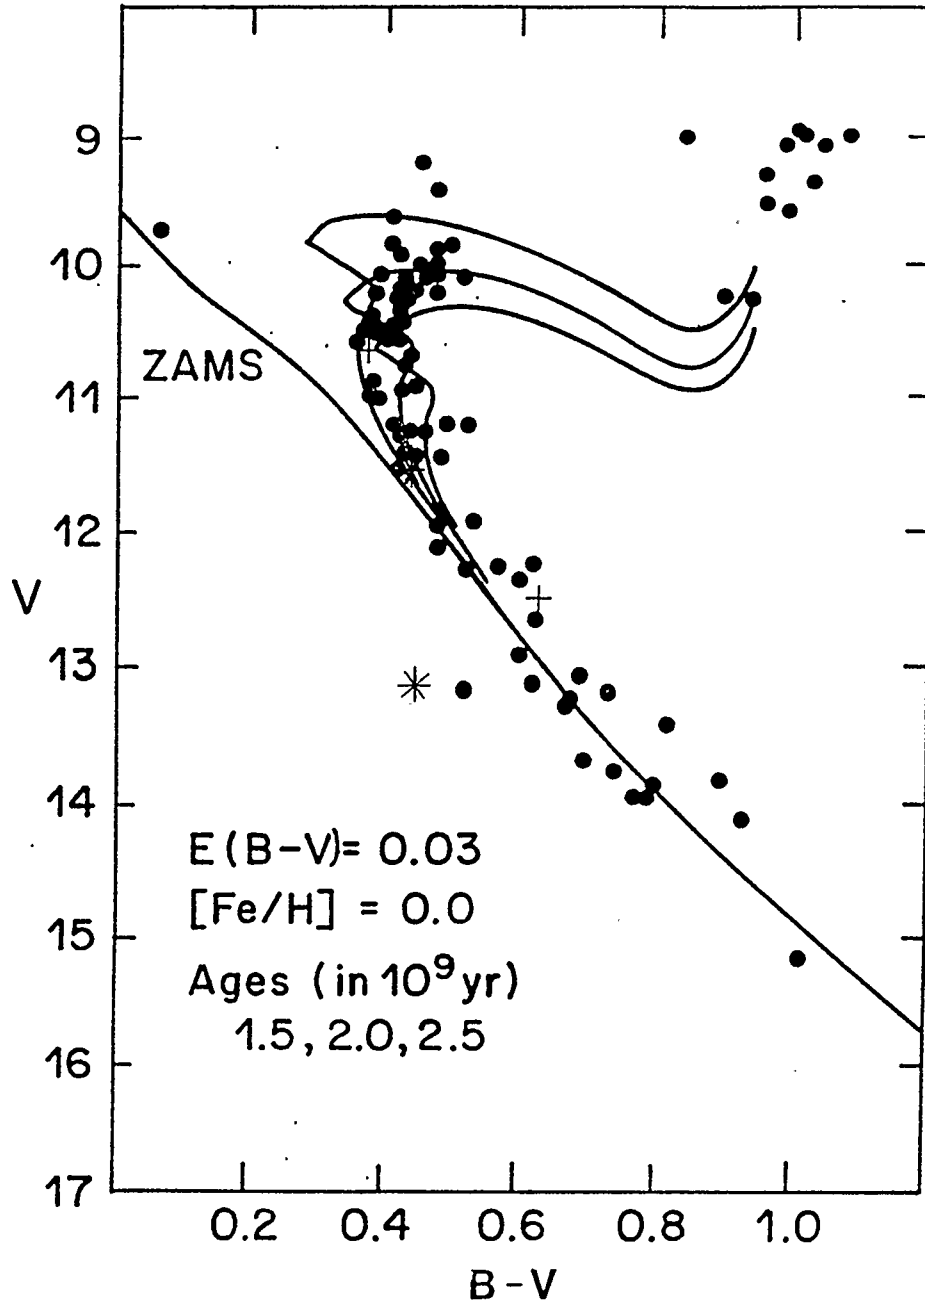

Figure 6 - The colour magnitude diagram of the open cluster NGC 752. The + symbols represent the components of DS And, a detached eclipsing binary. The * symbols represent the components of H235, a contact binary system. The lines indicate the isochrones of Vandenberg (1985).

certain models have set the age of some clusters greater than some estimates of the age of the universe, testing is obviously required.

The study of binary stars in globular clusters is also important for another reason. The presence of binary stars can fundamentally influence the dynamical evolution of the globular cluster. In the absence of counterbalancing forces, a globular cluster will inevitably experience *core collapse*, in which the central portion of the cluster collapses towards infinite density and temperature while the outer regions expand. However, attempts to model the dynamical evolution of clusters have shown that the presence of binary systems, whether primordial or formed during the cluster's collapse, will change the evolution of the cluster before the collapse is complete.

Interactions between binaries and other stars release binary star orbital energy, which serves to “heat” the cluster. This heating effect will slow down the collapse and ultimately cause cluster re-expansion. The precise nature of the heating depends on the type of binaries considered. The binaries can be broadly grouped into three classes, each with a qualitatively different heating mechanism: three-body binaries, tidal capture binaries, and primordial binaries. The former are binaries formed through three-body encounters. They are expected to be few in number and located preferentially in the densest cluster regions. Tidal capture binaries are binaries that pass close enough to each other (about three stellar radii (McMillan 1991)) that they become tidally bound due to energy transfer from the orbit to stellar oscillations. Primordial binaries are binaries that formed at the time of the cluster formation. It is difficult to say which of these types of binary is the most important to cluster heating because most attempts at simulation give differing results depending on the technique used and the assumptions made. Nevertheless, McMillan (1991) argues that if a cluster contains a substantial population of primordial binaries, they can come to dominate the cluster dynamics and terminate core

collapse well before three-body or tidal binaries can form. Thus far, binaries in clusters have been relatively hard to find but the results of Heggie & Aarseth (1992) indicate that a primordial binary frequency as low as 3 percent can fundamentally change the cluster evolution.

Yet another reason for interest in binary systems in globular clusters is their relation to the long standing puzzle of the origin of *blue stragglers* (BSs). Blue stragglers are stars that lie above and blueward of the main-sequence turn-off region of CMDs. If these stars had been normal single stars, they would have evolved away from the main sequence with the rest of the stars that at one point had similar luminosities. Hence, they seem to *straggle* behind their companions in the evolutionary process. In the first modern study of M71, Arp & Hartwick (1971) pointed to the work of others (Hoyle 1964, McCrea 1964, Cannon 1968, Strom & Strom 1970), who suggested that BSs were the result of close binary evolution, to possibly explain M71's BS population. This explanation continues to be very popular. One theory that has been directly supported by observations (Mateo *et al.* 1990) suggests that BSs have increased their main-sequence lifetimes by gaining material through mass transfer from a binary companion. Another theory suggests that BSs are actually the product of mergers with a binary companion. The merger would require angular momentum loss, possibly through tidal coupling, gravitational radiation, or magnetic stellar winds. Binary stars also play a role in the collisional theory of BSs because star-binary and binary-binary interactions are much more likely than single star collisions (Leonard & Fahlman 1991). Even if these interactions do not result in immediate mergers, they can result in the *hardening* of binary systems (*i.e.*, the period of the system is reduced) which will accelerate the merger process through other means (Hills 1984, 1990). For recent reviews of BS theories see Stryker (1993), and Livio (1993).

2.0 THE GLOBULAR CLUSTER M71

M71 (NGC 6838) is a small, relatively sparse, metal-rich globular cluster near the galactic plane. Because of its proximity and moderate reddening, M71 is important as it can provide an accurate colour-magnitude diagram (CMD) to act as a comparison for other metal-rich clusters, about which relatively little is known concerning their early evolution and age dispersion. See Table 1 for a list of cluster properties.

It has been argued (Zinn 1985) that there are two populations of globular clusters, which are distinguished at least in part by metallicity. The *halo* population is largely metal-poor while the *intermediate* population is comparatively metal-rich ($[\text{Fe}/\text{H}] > -0.8$). The cluster M71 falls into the latter category. Reviews of the metallicity of M71 by Zinn & West (1984) and Burstein *et al.* (1986) conclude that $[\text{Fe}/\text{H}] = -0.58 \pm 0.08$ and ~ -0.6 respectively. More recent estimates for $[\text{Fe}/\text{H}]$ range from -0.2 (Buser & Kurucz 1992) to -0.79 (Snedden *et al.* 1994). Allen & Martos (1988) have shown by numerically integrating the cluster's orbit backwards, that M71 has a very similar orbit to the open cluster M67. This is also consistent with M71 being a member of the comparatively disk-like intermediate population. M71 is also grouped with the galactic clusters rather than the globular clusters in Allen & Martos' sample when metal abundance is plotted against apocentric distance, pericentric distance, and orbital eccentricity. Some caution is necessary, however, because the proper motions they used, derived by Cudworth (1985), are uncertain at nearly the 50% level. If true, these kinematics results, coupled with the relative richness, would tend to suggest that M71 is comparatively young among the globular cluster population.

Arp & Hartwick (1971) conducted the first modern study of M71 and noted the scarcity of subgiant sequence stars, complicating the age determination for M71, which is

TABLE 1
M71 Properties

Property	Value	Reference
Right ascension, α_{1950}	19 ^h 51 ^m 33 ^s	A

still a matter of some controversy. They estimated the age to be 7.6 (+3.1, -2.3) Gyr on the basis of their derived turn-off luminosity. The sparse subgiant sequence has led others to attempt relative age estimates by comparing M71 with 47 Tuc, a similar, but well-studied cluster with an age estimated to be 13.5 ± 2 Gyr (Hesser *et al.* 1987). Hodder *et al.* (1992) concluded that M71 and 47 Tuc had similar ages while Heasley & Christian (1991) found M71 to be roughly 3 Gyr older than 47 Tuc. Davidge & Simons (1994) estimated an age of 16 Gyr based on their near-infrared CMD but caution that their conclusions should be considered tentative given uncertainties in metallicity and the current level of stellar physics knowledge.

The existence of blue stragglers in M71 was noted by Arp & Hartwick (1971). They observed a fairly well-defined extension to the main sequence and were surprised to discover that BSs were about as numerous as members of the subgiant sequence. To explain this, they noted M71's resemblance to the disk population and the suggestion of Abt & Levy (1969) that disk populations may contain a higher percentage of binaries. Therefore, they postulate that the BSs may be the result of close-binary evolution. More recently, Richer & Fahlman (1988) identified over 50 BSs using deep CCD photometry of $6' \times 4'$ area (as well as a sequence of white dwarf candidates). They also found that the binary frequency in the cluster centre is low, which would seem to contradict the hypothesis of Arp & Hartwick. On the other hand, the centrally flat surface density profile and high degree of mass segregation which Richer & Fahlman (1989) found were not explainable by Druker *et al.* (1992) using dynamical models in which core reexpansion is driven solely by three-body binaries. They suggest that additional physics such as the effects of primordial binaries may be required.

Four variable stars in M71 were identified by Sawyer Hogg (1973); one of these was an eclipsing binary. The latter, however, was shown to be a field star by Liller &

Tokarz (1981) by virtue of its radial velocity. Cudworth (1985) found two additional variables which, in addition to Sawyer Hogg's cluster variables, lie near the end of the red giant branch. Hodder *et al.* (1992) found four other variables with varying probabilities of membership based on CMD position. None of these systems have radial velocity measurements. One star (H3) may be a W UMa binary and a second (H4) was suggested to be an eclipsing binary of a non-W UMa type which so far have proved to be very rare in globular clusters. The light curves of both of these stars suffer from incomplete phase coverage, however, making their classifications tentative. Three of the five binaries, the analysis of which is the topic of this thesis, were discovered by Yan & Mateo (1994). The other two (V3 and V4) coincide with Hodder *et al.*'s suspected binaries and confirm their tentative classifications. The issue of cluster membership for all the binaries is not definitively settled, but Yan & Mateo conclude that the five binaries are all probable members based on three tests. The first test calculates how many contact and Algol-type binaries are expected in the line of sight out to a distance of 20 kpc. They find the total number of expected binaries to be 0.11 and 0.04 for contact and Algol binaries respectively. Their second test consists of calculating the luminosities of the systems (using radii calculated from Roche criterion and effective temperatures) and hence finding their distance moduli. In all cases, they found the distances to be consistent with cluster membership. The final test utilized Rucinski's (1994) calibration of absolute magnitude of contact binaries. Again, the results are consistent with cluster membership. The results of the current work, presented in Chapter 5, tend to confirm their conclusions, with the exception of V3, which appears to be closer than the other four variables.

3.0 DATA ACQUISITION AND REDUCTION

3.1 Acquisition

The data reduction discussed in this chapter was applied to data obtained at the Mount Laguna Observatory 1m telescope jointly operated by the San Diego State University and the University of Illinois Astronomy Departments⁴. Although much time was spent on the reduction of these *charged coupled device* (CCD) data, accurate results proved more difficult to extract than originally anticipated due to poor seeing and guiding conditions, the extreme faintness of the stars, and the crowding in the field. While these numerous, 5-colour data continue to be analyzed and will provide important additional information, higher precision 2-colour light curve data from the 1.5m Palomar telescope were made available by Lin Yan and Mario Mateo in advance of their own publication (Yan & Mateo, 1994). Their data come from 328 Johnson V and Gunn i CCD images, covering a 6.3'×6.3' field, taken during 4 nights in 1991 and 11 nights in 1993. Tables 2a and 2b show the positions and basic properties of the five eclipsing binaries that were found using these images. Figures 7a through 7j show the light curves of these binaries. A more detailed description of the data and reduction procedure can be found in Yan & Mateo, 1994. However, the procedure is similar to that performed on the larger Mt. Laguna set.

⁴ The Mt. Laguna CCD has the following properties: 800×800 , $15 \mu\text{m} \times 15 \mu\text{m}$ pixels; conversion gain, 1.7 electrons/adu (analog to digital unit); read noise, 7 adu; and linearity to 32,000 adu.

Figure 7i - The Yan & Mateo Johnson V light curve of M71-V5 with photometric errors.

Figure 7j - The Yan & Mateo Cousins I light curve of M71-V5 with photometric errors.

Because the reduction of CCD data is essential to the quality of the resulting light curves, and because the success of the analyses depends on that quality, the reduction process will be discussed in detail here.

3.2 Reduction

The reduction of, and magnitude determination from, CCD images is a difficult process and some discussion is illuminating. The process required to go from raw CCD images to usable stellar magnitudes can be divided into three stages. The first stage is the image reduction in preparation for stellar magnitude determinations by removing noise, defects and anomalous count source signatures. The second stage is the determination of magnitudes by one of several methods. The third stage is the correction of the magnitudes for atmospheric extinction and conversion from a local system to a standard system.

CCD photometry has many advantages over single-channel photoelectric photometry (PEP): simultaneous observation of several sources; spatial resolution for extended objects; simultaneous sky background measurement; and the ability to recover individual images from superimposed images. But with those advantages come significant disadvantages. The most important is a decrease in the signal-to-noise ratio per pixel. A second potentially important disadvantage is the much larger memory storage space required for data acquisition and processing and a corresponding increase in time required for reduction. A moderately successful CCD photometry observing run can often yield gigabytes of data and take months to reduce whereas even a long PEP observing run will often yield less than a single megabyte of data and can be reduced in a single day. The reasons for this are: (1) a CCD image contains the equivalent of n PEP observations in a two dimension array (where n is the number of pixels); and (2) the reduction procedure requires a great number of extra images in order to reduce the influence of noise and sensitivity variation across the CCD. Since typically $n \approx 512^2$ or 800^2 , and light curves usually require ~ 200 points per passband, the requirement for gigabytes of storage space is obvious. However, much of the information contained in a CCD image is ultimately not needed, at least in the case of CCD photometry.

Before discussing the reduction procedure in depth, it is informative to briefly mention the topic of noise. There are potentially many contributors to the uncertainty in a CCD measurement, the three most common of which are discussed here. A more detailed description of these and other noise sources can be found in Gilliland (1992). One very fundamental source of noise is the statistical variation in the number of detected counts. The uncertainty associated with photon counting is Poissonian in nature. Photons from a constant source do not arrive at a uniform rate. They are instead randomly clumped so the number of photons detected in any given time interval will vary. In addition, detectors

only register a certain fraction of the photons that strike them (this fraction is called the *quantum efficiency* and it varies with wavelength and from CCD to CCD). Shot noise is a measure of the width of Poissonian distribution expected if the same measurement was taken repeatedly. Any measurement will have a root mean square (rms) variation of at least the square root of the number of recorded photons. Therefore, if the number of electrons that represents the brightness of a star is given by C_{star} , the rms noise level can never be less than $C_{\text{star}}^{1/2}$. A second noise source is the shot noise associated with the background contribution to the measurement. If this contribution is given by C_{sky} , the associated noise will be $C_{\text{sky}}^{1/2}$. The importance of this quantity clearly depends on the brightness of the sky, but it also depends on the size of the stellar image. The sky contributes signal to each pixel of the CCD frame so the amount of signal contributed to a small stellar image will be less than that contributed to a large stellar image. The final noise contribution to be discussed is created in the process of electronically measuring the charge level of each CCD pixel. When the signal generated by light falling on a CCD is collected, amplified, and digitized, noise is introduced. This is known as *read-out noise*, R . It is a per-pixel quantity and is typically a few electrons to a few tens of electrons (root mean square variation), depending on the CCD. Again, the significance of read-out noise for CCD photometry depends on the size of the stellar image since it is a per-pixel quantity. Each of these noise contributions add in quadrature so the signal-to-noise ratio of a measurement is expressed as

$$S / N = \frac{C_{\text{star}}}{\sqrt{C_{\text{star}} + N_{\text{pix}} \cdot (c_{\text{sky}} + R^2)}}, \quad (22)$$

where N_{pix} is the number of pixels occupied by the stellar image and c_{sky} is the number of background counts per pixel in the region of the stellar image. When the noise is dominated by the sky contribution—as might be the case when observing under a bright

moonlit sky or when observing near an urban centre—the data are said to be sky-limited. When the noise is dominated by read-out noise, the data are said to be read-noise-limited.

There are three common types of images required for the preparation stage, usually referred to as *bias frames*, *dark frames*, and *flats*. Bias frames are zero second, or as close to zero second as possible, closed-shutter exposures. They are intended to measure any spatial pattern in the zero point of the CCD images. This pattern, if it exists and does not change with time, is referred to as the *bias structure*. The amplitude of the bias structure is generally expected to be quite low, and is sometimes exceeded by read-out noise. The frames will often have a large (several thousand electrons per pixel) zero point offset that is not spatially dependent, however. This offset can be subtracted off and does not contribute Poissonian (shot) noise to the image. If the bias frames are dominated by read-out noise, they can be used to determine the read-out noise, if it is not already known, by forming a histogram of the number of pixels versus count level. This will yield a Gaussian distribution with a standard deviation equal to the read-out noise.

Dark frames are also closed-shutter exposures but they are of durations typical of normal exposures. Their purpose is to measure any dark current that might exist, which is expected to be position dependent. To this end, ideally one would take a dark frame of equal duration for every program frame. However, this is impractical when rapid time-variations are to be investigated. Alternatively, one can obtain many dark frames, sampling a wide range of exposure times for each night of the observing run when conditions (such as clouds or daylight) preclude observations of program or calibration objects. Fortunately, such time-consuming procedures are not usually necessary because the dark current exhibited by most CCDs is not important provided the temperature of the chip is low. Furthermore, many CCD systems have an unexposed strip along one side

which effectively measures the dark current offset if not the detailed structure. This is the case for the Mt. Laguna chip.

Flats are intended to measure the variation on the gain of the CCD from pixel to pixel and are produced by observing a uniform source. The best uniform source to use for this purpose is the source of much controversy. The most common types of flats are *dome flats*, *twilight sky flats* and *dark sky flats*. Dome flats are produced by observing an illuminated screen inside the dome. Often the light source illuminating the screen is changed for each filter for which observations are taken. Twilight sky flats are produced by observing the sky in twilight, hopefully when the sky is bright enough that stellar contributions are negligible but not so bright that the CCD saturates. Dome flats have the advantage of not needing constantly changing exposure lengths as the sky brightness changes, not to mention the fact that they can be done during the day (provided the dome is light tight against daylight) or during weather not suitable for observing program objects. However, some observers prefer sky flats because the sky is closer in colour to certain program objects (such as the metal-poor stars of globular clusters) than are the projector lamps used to illuminate dome flats. Other observers feel that the wavelength dependence of the CCD sensitivity requires that flats be taken under precisely the same conditions as the program frames, *i.e.*, with the night sky itself. Such dark sky flats are produced by observing a "blank" region of sky, one in which there are relatively few stars. Acquiring several of any type of frame is always an advantage because statistics can be improved and cosmic rays can be medianed out (using several offset frames), but it is especially important for dark sky flats because regions that appear blank may actually contain unnoticed faint stars which must be medianed out if the flats are to be of any use. A very important disadvantage of dark sky flats is that extremely long exposures are required to acquire significant signals, particularly in shorter wavelength passbands. If

long exposures are not used, any advantage gained by using this method will almost certainly be lost due to large Poissonian error.

Although many software packages are available, the Mount Laguna images discussed here were all reduced with the aid of the widely used Image Reduction and Analysis Facility (IRAF), developed at the Kitt Peak National Observatory, Tucson, Arizona.

Before anything can be done with these frames or with the program images, each must have its zero-point offset and large scale *bias structure* removed. The IRAF package COLBIAS (for ‘column bias’; a ‘row bias’ task is also available) is extremely useful for this purpose. The package fits one of four functions to the bias region of the frame (the region that is not exposed), subtracts the bias level from the entire CCD, and trims the bias region from the image.

Once this has been done, the smaller scale bias structure is determined. To this end, the bias frames should be averaged using the task IMCOMBINE (for ‘image combine’). If there is no significant change in bias frames as the night progresses or from night to night, all bias frames can be used to produce a single averaged frame. A median average is best because it will remove any one-time occurrences such as cosmic ray hits and random noise that are not representative of the bias structure. This requires at least three bias frames but considering that they require little time to produce, a considerably larger sample is preferable. This method of cosmic ray removal and statistics improvement is extremely fast and effective and so is used whenever at least three identical frames are available.

The median COLBIASed bias structure can be used next to prepare the flats, once their DC offset has been removed with COLBIAS. The bias structure can then be simply subtracted using the task IMARITH (for ‘image arithmetic’). The flats are then averaged.

Again, a median is the preferred statistic but this requires at least three images per filter. Because the flats measure the multiplicative gain variation from pixel to pixel, it is desirable to scale the images by their respective modes before the median is performed in order to make their ranges roughly similar⁵. To account for images with varying counts having differing shot errors, the images should also be weighted by their respective modes. This scaling and weighting can be done in one step using IMCOMBINE. The final step is to divide the median flat for each filter by its mean using IMARITH. This normalizes the flat and is done in order to avoid drastically changing the level of the program images when the sensitivity structure is divided out.

The program images can now be reduced. Once again, the zero-point offset and large scale bias structure is subtracted off with the use of COLBIAS and the median residual bias structure is subtracted off using IMARITH. The sensitivity structure is then divided out with the use of IMARITH by dividing the program image by the normalized median flat (the pixel values of which are of the order of unity) for the appropriate filter. It is important to properly remove the zero-point offset before dividing by the flat because failure to do so may produce an image that is worse (less flat) than the program image that has not been divided by the flat. Another possible reason for a non-flat resultant image is the variation of some element in the telescope-CCD system (see Figure 8). However, as long as the program objects appear many times brighter than the background fluctuation, the magnitude determination should not be drastically affected.

⁵ It would be more intuitive to scale the images by their exposure times but this would produce meaningless results unless the source was identical from image to image. This is clearly not the case for sky flats and might not be the case for dome flats unless precautions to ensure uniformity are taken, so it is easier and safer to scale by the mode.

Figure 8 - An example of imperfect flat-fielding. The large rings are most likely a result of dust settling in the telescope-CCD system.

Up to this point, the effects of cosmic rays have not been discussed because they are removed when several images are medianed together. However, one usually does not have several identical program images that can be combined. In fact, if one did not have at least three biases or flats which could be combined, the following procedure would need to have been used in the earlier reduction stages. Inspection and editing of cosmic ray signatures in each frame is the most accurate method of cosmic ray removal but is excessively tedious. The scanning of several hundred 800x800 CD images and manual smoothing of cosmic ray spike regions is not practical. However, this process can be automated through software. The IRAF task COSMICRAYS scans the image for the characteristic signature of a cosmic ray hit: one or a few pixels that stand out well above the surrounding pixels. The task COSMICRAYS smooths out pixels that exceed the mean of the surrounding pixels by a user-defined threshold (typically 5σ) and also have a ratio of the mean neighbouring pixel level to the candidate pixel level less than a second user-defined threshold (typically 2 to 10 percent). If the first threshold is not set properly, either cosmic rays will go undetected or spurious spikes will be mistaken for cosmic rays, unnecessarily slowing the reduction process. If the second threshold is set too low, again, many cosmic rays will not be found, and if it is set too high, stellar images can be mistaken for cosmic rays. The latter possibility is especially important to consider if the image scale and seeing is such that a stellar image occupies only a few pixels.

3.3 Magnitude extraction

Once the images are reduced to the stage that one can be confident that the number of counts in any given image pixel is linearly related to true intensities and that this

relationship does not vary significantly from pixel to pixel, the process of measuring the brightness of the program objects can begin.

There are many ways that this can be done and the most appropriate strategy will depend on the nature of the image under consideration. In the case of the fairly sparse standard star fields, simple aperture photometry was deemed sufficient. This process involves the counting of photons within a set of concentric apertures and 'sky' annuli of specified size centred on each star image. This was carried out using the IRAF task APPHOT (for aperture photometry). Several aperture sizes were selected and then each star was manually selected by visual inspection. The task's automatic centroiding option was used to avoid inadvertent errors in aperture positioning.

In the case of the Mount Laguna M71 images, the field was extremely crowded and so it was decided that *point spread function* (PSF) magnitudes would be preferable to aperture magnitudes. Peter Stetson's DAOPHOT II (a 1993 upgrade to the earlier DAOPHOT) program, and its ancillary programs, were used for this purpose. The less well-known program DoPHOT (Mateo & Schechter 1989) was also considered but difficulties in adapting this package to our workstations and other considerations made the more familiar DAOPHOT II a better choice. A comparison between these packages was carried out by Janes & Heasley (1993), who concluded that the programs, along with their own software, all produce comparable results, such that ease-of-use issues of one package over another tend to be the limiting consideration.

DAOPHOT requires certain information:

- the approximate size or full-width at half-maximum (FWHM) of the objects in the frame
- the number of photons corresponding to an analog-to-digital unit (ADU)
- the readout noise per pixel

- the saturation level, beyond which the detector no longer operates linearly

Knowing this information, DAOPHOT will, with variable levels of interaction, locate star-like objects in the frame above a certain threshold detection level; perform aperture photometry for these objects with a range of concentric apertures, estimating a local sky brightness for each object; and obtain a PSF for the frame by averaging several stars. At this point the auxiliary program ALLSTAR II can be used. ALLSTAR computes precise positions and magnitudes by fitting the PSF to each object. It then subtracts the fitted images from the real images to allow for the location and measurement of previously undetected objects.

3.4 Extinction and transformation

Almost all empirical information in astrophysics is obtained by studying the electromagnetic radiation received from astrophysical objects. Aside from the direction from which the radiation comes, the most obvious measurement that can be made is its brightness, more specifically, its brightness at various wavelengths. If anything is to be learned from these measurements, the relationship between the amount of radiation received and the amount emitted at the source, and how this light has been changed, must be understood. There are many factors that influence this relationship, including the distance of the source, interstellar extinction, the speed at which the source is moving, *etc.* However, before most of these factors can be taken into account accurately, usually one must consider other quite local problems. Every observatory on earth is affected, and affected differently, by: (1) the path length through the earth's atmosphere; and (2) the equipment used to measure the radiation. Therefore, one of the first steps in interpreting astrophysical data for earth-bound observers is to measure, understand and minimize these locally caused effects. There are two parts to this problem in the case of magnitude

measurements: correction for the atmospheric extinction; and the transformation of the corrected magnitudes from the instrument's system to a standard system. Although these two steps are largely necessitated by different effects, the procedures for extinction correction and transformation are linked: both involve transformations. What follows is a quick derivation of the extinction and transformation equations. For an in-depth discussion of these equations, see Hardie (1962).

Light traveling through any material will lose a certain amount of intensity. This loss of intensity, dI , is related to the incident intensity, I , the amount of material it transverses, dx , and the absorption/scattering coefficient of the material, κ , by:

$$dI = -I \cdot \kappa \cdot dx. \quad (23)$$

Integrating this expression through the entire path length, x , gives:

$$\log I_f = \log I_o - \kappa x, \quad (24)$$

where I_f and I_o are the final and initial intensities. In magnitudes, this equation becomes

$$m_o = m - 2.5\kappa x = m - kX, \quad (25)$$

where m_o is the magnitude outside the atmosphere, m is the observed magnitude, k is the extinction coefficient in units of magnitude per airmass, and X is the airmass. Airmass is essentially a measure of the path length of atmosphere through which the light passes. It is expressed in units of the zenith thickness of the atmosphere at the location of the observer. It can be expressed, to a first approximation, as

$$X = \sec z, \quad (26)$$

where z is the zenith distance, the angle of separation between the zenith and the object of interest. This equation is based on the approximation of a plane parallel atmosphere and is accurate to 0.01 of an airmass at zenith distances up to 65 degrees. For more accurate calculations at larger zenith angles, the equation

$$\begin{aligned}
X &= \sec z - A(\sec z - 1) - B(\sec z - 1)^2 - C(\sec z - 1)^3 \\
A &= 0.0018167 \\
B &= 0.0028750 \\
C &= 0.0008083
\end{aligned}
\tag{27}$$

can be used (Hardie 1962).

The colour of an object is also affected by the amount of atmosphere through which its light must travel. An equation similar to (25) can be used for colour indices:

$$c_o = c - k_c X, \tag{28}$$

where c is a colour index and the subscript o denotes outside atmosphere values. The extinction coefficients k and k_c are actually functions of the object's light distribution and so it is more accurate to write:

$$m_o = m - k'X - k''cX \tag{29}$$

$$c_o = c - k'_c X - k''_c cX \tag{30}$$

where k' , k'_c and k'' , k''_c are the principal and second-order extinction coefficients. The second-order coefficients are found to be fairly constant, even though, in principle, the coefficients can vary significantly.

There are several methods of determining extinction coefficients which require differing amounts of time and sky conditions. The Hardie method, described here, requires a generally uniform sky but is also quite quick to perform, leaving most of the night for observing program objects.

If two known stars are observed, one of which is observed through a low airmass and the other through a high airmass, equations (29) and (30) can be re-expressed differentially:

$$\Delta m_o = \Delta m - k' \Delta X - k'' \Delta(cX) \tag{31}$$

$$\Delta c_o = \Delta c - k'_c \Delta X - k''_c \Delta(cX). \tag{32}$$

If approximate values are assumed for the second-order coefficients, which in general are fairly constant, then these equations are easily solved for the principal coefficients. The effect of inaccurate second-order coefficients can be minimized by selecting stars that are closely matched in colour indices. For increased accuracy, several sets of high-low stars can be observed and the principal coefficients can be found with a least-squares method. Observing three sets of stars usually yields principal coefficients accurate to 2 or 3 percent.

Unfortunately, the fact that equations (31) and (32) contain outside-atmosphere magnitudes and colour indices complicates matters considerably. Unless the telescope used is very close to a standard system, these values will not be known. For simplicity, all further discussion will use notation specific to the UBVI system used for the Mount Laguna data. This does not, however, affect the generality of the method described. Using the equations:

$$V = v_o + \mu_v(B - V) + \zeta_v \quad (33)$$

$$C = \mu_c c_o + \zeta_c, \quad (34)$$

which are usually adequate to transform from one system to another provided the systems are reasonably similar and extremely high wavelengths and stellar temperatures are avoided, the outside-atmosphere magnitudes can be found. Here, all upper case letters refer to the standard system—the colour indices C are $(B-V)$, $(U-B)$, $(V-R)$, and $(V-I)$ —and μ and ζ are the transformation coefficients and zero-point respectively. Differentially, these equations are:

$$\Delta V = \Delta v_o + \mu_v \Delta(B - V) \quad (35)$$

$$\Delta C = \mu_c \Delta c_o. \quad (36)$$

The zero point has been eliminated but if the transformation coefficients are not known, an iterative procedure of successive approximation must be used to calculate μ , ζ , and k' simultaneously. By combining equations (31) and (35) and equations (32) and (36), the equations used for the iterative procedure are obtained:

$$k'_v \Delta X = \Delta v - k''_v \Delta[(b - v)X] + \mu_v \Delta(B - V) - \Delta V \quad (37)$$

$$k'_c \Delta X = \Delta c - k''_c \Delta(cX) + \Delta C \mu_c^{-1}. \quad (38)$$

To iterate, the equations are solved for one unknown, k'_v for instance, and an enlightened guess is used for the second unknown ($\mu_v=0$, $\mu_c=1$ for example). The resulting value for k'_v is then used to calculate μ_v , which in turn is used to find an improved value for k'_v and so on.

Once the extinction and transformation coefficients are known, the program object magnitudes can be corrected for extinction and transformed to the standard system of magnitudes so that comparisons with the work of others or the work from other telescopes are meaningful.

4.0 LIGHT CURVE MODELLING

4.1 The modified Wilson-Devinney modelling code

The light curve modelling program that forms the bulk of the code used for this work was written by Robert E. Wilson and Edward Devinney and was first described in 1971 (Wilson & Devinney, 1971). Since then, numerous additions and improvements have been made (Wilson 1979, Milone *et al.* 1992, Stagg & Milone 1993, Stagg *et al.* 1994) to arrive at the version used for this work. Some of the more important new features are: the handling of eccentric orbits, the ability to include and adjust star spots, the use of Kurucz's modern stellar atmospheres (Milone, 1993) integrated over appropriate passbands, several modes of operation depending on the type of binary system (i.e., contact, semi-detached, detached, x-ray binaries), and a dramatic increase in speed thanks to more efficient code. The usage of the Wilson-Devinney code has grown considerably since its introduction—being used in roughly 50 percent of the light curve solutions carried out between 1987 and 1990 (Wilson 1990). Thus this program is the one of choice, especially in the exploration of properties of binary systems involving non-solar compositions. A discussion of light curve modelling software and comparisons between existing programs may be found in Milone (1993).

The University of Calgary version of the Wilson-Devinney modelling program (hereafter, WD) joins the light curve calculation program (LC) and the differential corrections program (DC) but the two still remain essentially independent. The two subprograms have different purposes but both are an integral part of the modelling process. The appropriate subprogram to be used is signaled by an initial control integer in the input file.

LC, as previously mentioned, is used to calculate light and radial velocity curves based on the parameters supplied within the input file. This is accomplished by dividing the surface of the stars, as described by a Roche equipotential model, into a grid. In the case of light curves, it is then determined which grid points will contribute light to the calculated light level for each phase point: parts of the surface of a star that are occulted by the other star or by another part of the same star cannot contribute except for light reflected off the other star. The grid points that are visible to the observer contribute to the total light level for the current phase of the light curve according to temperature, limb darkening, gravity darkening, and the amount of light from the other star that is reflected in the direction of the observer. Radial velocity curves are calculated in essentially the same manner. However, for the current work, no velocity data were available so the synthetic RV curves are primarily useful only for predicting RV curves for observation planning and for testing the model against subsequent RV data.

An example of an LC input file is given in Appendix B. The input file is identical to the standard LC input file, a full description of which can be found in the WD manual (Wilson 1992), with the exception of the first few lines. The lines up to and including the first occurrence of "END", the first five lines in the example given, are related to the University of Calgary enhancements to the WD code. Rather than having two separate programs (LC and DC) containing redundant subroutines, a single program is used. The first line of the input file contains a 1-digit integer and indicates whether LC or DC is to be run (1 for LC, 2 for DC). The second line contains the logarithm of the surface gravity (in CGS units) for each component. The third and fourth lines contain the names of the files containing the ratios of the integrated passband fluxes to the monochromatic blackbody fluxes for a range of temperatures and surface gravities. These files correspond to the synthetic light curves requested later in the input file. An example of a flux file is given in

Appendix C. The flux ratios are based on the 1993 model atmospheres of Kurucz and are specific to the passband in question and metallicity. The use of modern model atmospheres addresses what has long been a weakness of the WD code. In the example given, two files are listed, one for each synthetic light curve requested later in the file (Johnson V [Fe/H]=-0.3 and Cousins I [Fe/H]=-0.3). If more light and velocity curves are present, there must be a corresponding number of flux files listed, and they must appear in the same order as the curves appear in the file. The fifth line in this example signifies the end of the flux ratio file list. The surface gravities and temperatures (contained in the standard part of the LC and DC input files) are used to interpolate among the Kurucz models in the flux files for the appropriate ratio of atmospheric to blackbody fluxes.

The DC subprogram is for determining differential corrections to the modelled parameters. The corrections to the adjusted parameters are obtained from a least squares analysis, the equation of condition for which is

$$\Delta L = \frac{\partial L}{\partial x_1} \Delta x_1 + \frac{\partial L}{\partial x_2} \Delta x_2 + \frac{\partial L}{\partial x_3} \Delta x_3 + \dots, \quad (39)$$

where x_i are the adjusted parameters. The process requires the generation of at least $m+1$ synthetic light curves for each wavelength, where m is the number of adjusted parameters. Asymmetric partial derivatives require $m+1$ synthetic light curves and are calculated according to

$$\frac{\partial L}{\partial x} = \frac{L(x + \Delta x) - L(x)}{\Delta x}, \quad (40)$$

where Δx is a controllable step size. Symmetric partial derivatives can also be used but they require $2m+1$ synthetic light curves and are calculated according to

$$\frac{\partial L}{\partial x} = \frac{L(x + \frac{\Delta x}{2}) - L(x - \frac{\Delta x}{2})}{\Delta x}. \quad (41)$$

This method of finding light curve solutions has its limitations, as was noted in some detail by Kallrath & Linnell (1987). In particular, many of the adjusted parameters are often strongly correlated which may lead to the failure of the differential corrections to converge on a solution. To avoid this, DC allows the calculation of corrections for subsets of uncorrelated parameters. Since the partial derivatives are already calculated for the main parameter set, the subsets require little extra time. However, having multiple subsets of uncorrelated or weakly correlated corrections rapidly leads to numerous possible search branches, the exploration of which can be tedious. One might have some faith that all of the search branches would eventually lead to the same minimum in parameter space since all corrections should in theory point downhill, even if they do not point in the steepest direction. However, it is often the case that uncorrelated correction sets yield worse fits than the initial parameter sets. In fact, even subsets with only one adjusted parameter, leaving no possibility of correlation, can give corrections that result in worse fits. This is probably due to limitations in the accuracy of the partial derivative calculations, particularly during final convergence. The WD code was originally written with these limitations in mind and automated iteration procedures were omitted intentionally for this reason. Careful subset selection and exploration will usually lead to a local minimum in parameter space but, without caution, convergence may take much longer than is necessary, or may not occur at all.

Unfortunately, finding a local minimum in no way ensures that a deeper minimum does not exist elsewhere in parameter space. This problem is traditional and persistent for DC because the program makes no effort to address it. Like a marble on an irregular surface, DC will always try to move to the nearest local minimum. If the initial set of parameters is not close to the best solution, as is very often the case, DC will have little hope of finding this solution. Of course it is possible to start DC in many locations in

parameter space and see where each search leads, but this requires a great deal of computer time and even more time and effort for the user. One stratagem that was used by Groisman (1989) and Milone *et al.* (1991) was to vary each parameter by $\pm 10\%$ in search of deeper minima. This method is useful, but changing one parameter at a time limits the search directions to the directions of the parameter axes and neglects the m -dimensional diagonals. Since many parameters are regularly correlated (T_2 and L_1 or Ω_i and q for instance), valleys along diagonal directions are to be expected.

An example of a modified DC input file is found in Appendix D. Again, the first five lines are recent additions to the standard DC input file. They are the same as described above, but here, the list of flux files must correspond with the observed light curves included in the standard portion of the DC input file rather than the requested synthetic light curves. The rest of the input file is the same as the standard DC input file; an illustration can again be found in the WD manual (Wilson 1992).

For all its limitations, WD, with the University of Calgary modifications, is the most powerful light curve analysis program available. The global minimum search can be met, at least to some degree, by an additional program.

4.2 The simplex search algorithm

The application of the simplex algorithm, as implemented by Kallrath & Linnell (1987), is an attempt to avoid many of the problems associated with the differential corrections method of optimization, which, for the most part, stem from the partial derivative calculations. Several *direct search methods*, which by definition do not require derivatives, are described by Murray (1972). Of these, the simplex algorithm as given by

Nelder & Mead (1965) becomes comparatively more efficient when more than two or three parameters are to be adjusted, as is the case for light curve modelling.

The simplex algorithm calculates an initial set of $m+1$ synthetic light curves, each representing a vertex of the simplex in m -dimensional parameter space. The size and location of the initial simplex is controlled by the user. The fit of each light curve, or point in parameter space, to the observed data is then determined. The simplex moves around in parameter space in search of the best solution according to four operations: *reflection*, wherein the worst of the $m+1$ vertices is reflected through the centre of the other m vertices to a new position; *expansion*, wherein the worst vertex moves away from by a controllable amount; *contraction*, wherein the worst vertex moves toward the centre of the other m vertices by a controllable amount; and *shrinkage*, wherein all the vertices move toward the best vertex by a controllable amount. Figure 9 is a flow chart which illustrates when each of these operations is used. A more detailed explanation of the simplex algorithm is given by Kallrath & Linnell (1987). In this fashion, the simplex “walks” about in an ordered but flexible manner until it converges to a minimum. Again, it cannot be guaranteed that the absolute minimum has been found but the simplex algorithm is much more far reaching than gradient dependent searches and due to its convenience of use, many searches can be started and left to run with little intervention from the user. A set of constraints on the variation of each parameter precludes non-physical results. The constraint conditions, and the circumstance that the best vertex is always retained, assures a sensible result. This compares favorably with automatic iteration with DC, were that program to be modified to permit automatic iteration. The gradient-free search method is also faster since each step usually requires a single new synthetic light curve calculation for the new vertex instead of the $m+1$ or more light curve calculations required by DC. By using the relevant parts of the WD code to generate the required synthetic light curves,

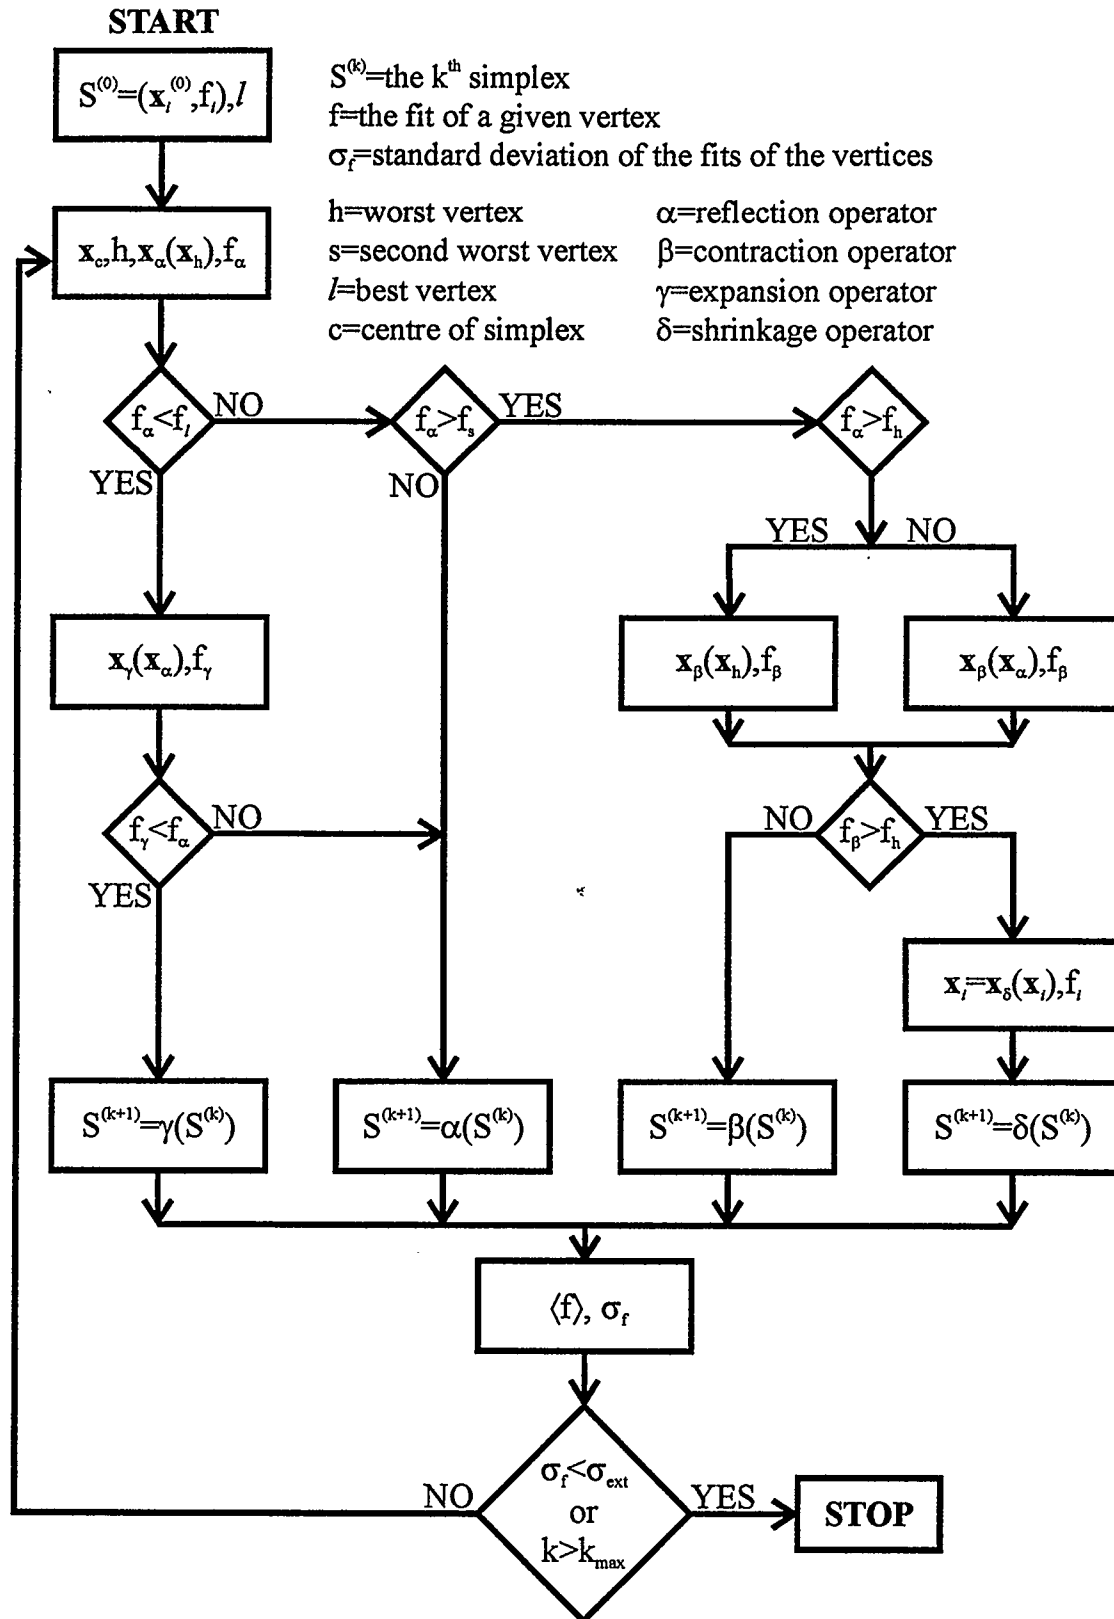

Figure 9 - A flow chart demonstrating the operation selection process for the simplex algorithm. Adapted from Figure 9 of Kallrath & Linnell (1987).

the results of the simplex parameter space searches are expected to be in agreement with the WD program. In practice, the simplex and WD programs are not in complete agreement but in the examples reported by Stagg & Milone (1993), the results agree within the uncertainties.

It should be noted that DC and other derivative dependent procedures, while suffering in overall efficiency (*i.e.*, efficiency from the user's perspective), due to the difficulty and number of calculations required, are actually more efficient in terms of convergence effectiveness because they use a directed search (*i.e.*, the number of steps required to reach convergence is expected to be smaller, even though the time required may be longer). It is often desirable, therefore, to switch from simplex to WD once the search has come close to the solution. Also, WD allows the determination of probable errors and the identification of poorly constrained parameters.

There are several files required to run simplex besides the main program. The input file, which generally has a 'dci' extension, is exactly the same as a modified DC input file, described above, with no subsets, since subsets have no meaning in the context of the simplex algorithm. The use of a DC input file is deliberate to facilitate comparisons between WD and simplex. The flux files specified in the dci file are also required. A second file containing the limits beyond which simplex will not allow parameters to move is called the constraint file, and generally has a 'con' extension. A third file, the information file, contains information such as the size of the initial simplex, coefficients for adjusting the way it moves and contracts, the parameters that are to be adjusted, and when the program is to stop (*i.e.*, after a certain number of iterations or when the simplex contracts to a certain size). This file generally has an 'inf' extension. Finally, the 'run' file is actually a small program that calls the main program and organizes the input and output files. All of these files except the DC input file are well organized and include some

explanatory text to avoid the formatting problems and confusion that are common with the somewhat cryptic DC input files. Examples of all these files are given in Appendix E.

4.3 Modelling procedure

The exact procedure used for modelling the light curves was dependent on the nature of the light curves and on how the modelling proceeded. The general procedure can be summed up as follows: (1) the calculation of initial parameter sets and preparation of input files; (2) the approximate location of the solution using simplex; (3) and the fine tuning of the solution using WD. These steps are discussed in detail for the present case below.

Of the five systems studied, four appear to be W UMa-type systems. Following the work of Rucinski (1973, 1974) the depth of the primary and secondary minima were measured and converted to normalized light units using

$$\frac{l_{1,2}}{l_{\max}} = 10^{\left(\frac{m_{1,2} - m_{\max}}{-2.5}\right)} \quad (42)$$

and

$$J_{1,2} = 1 - \frac{l_{1,2}}{l_{\max}} \quad (43)$$

The difference in the depths

$$\Delta = J_1 - J_2 \quad (44)$$

and the depth J_1 of the primary were then used to find approximate values for inclination i and mass ratio q by linearly interpolating from Table 1 of Rucinski, 1974. For this interpolation, it was assumed that the fill-out parameter f_R , defined by Rucinski as

$$f_R = \frac{\Omega - \Omega_{\text{outer}}}{\Omega_{\text{inner}} - \Omega_{\text{outer}}}, \quad (45)$$

was equal to 0.5. The total mass of each binary system was assumed to be 1.7 solar masses, roughly twice the turn-off mass of the M71 colour magnitude diagram according to the models of Bergbusch & Vandenberg (1992). An age of 14 Gyr and a metallicity of $[\text{Fe}/\text{H}] = -0.78$ were assumed as was suggested by Hodder et al. (1992). The use of this mass implies that each system consists of two main sequence stars near the current main sequence turn-off. There is little justification for this assumption but at the commencement of modelling, no other information was available. It will be argued in Chapter 5 that the use of this total mass is of no significant consequence for the usefulness of the final models, allowing more reasonable masses to be substituted later. With the total mass and periods for each system, the respective semimajor axes were then calculated using equation (4). Rough radii, R , were then calculated using Eggleton's (1983) approximation of effective Roche lobe radii:

$$\frac{R}{a} = \frac{0.49q^{-2/3}}{0.6q^{-2/3} + \ln(1 + q^{-1/3})}. \quad (46)$$

Note that this equation has been modified slightly in order to account for Eggleton's definition of q being the inverse of that used in the present work. Knowing the approximate radii, the surface gravities were estimated using

$$\log g = \log \left(G \frac{M_i}{R_i^2} \right). \quad (47)$$

The effective temperatures of the hotter star in each system, T_1 were estimated from the tables of Popper (1980) for Johnson (V-R) colour indices. These colour indices were determined from the Johnson V and Cousins I light curves supplied by Lin Yan (private communication) using the relationships:

$$(V - R)_{JC} = 0.505 \cdot (V - I)_{JC} + 0.707 \quad (48)$$

and

$$(V - R)_{JC} = -0.03206 + 0.71652 \cdot (V - R)_J. \quad (49)$$

Equation (48) was derived by fitting tabulated (V-R) colour indices against (V-I) values for the Landolt's (1983) standards (see Figure 10). Equation (49) was determined by Landolt (1983). Based on the differences between the temperatures derived in this manner and those derived by Yan & Mateo (1994), the uncertainty in T_1 was assumed to be 150 K. Further improvement in these values requires spectral classification but, given that the temperature difference between the primary and secondary overshadows the effects of small uncertainties in the absolute temperatures, later modelling attempts based on new temperatures are not expected to yield results greatly different from the present results. Once the effective temperatures and the surface gravities were estimated, bolometric, Johnson V, and Cousins I limb darkening coefficients (X_i^{bol} , X_i^V , and X_i^I respectively) were estimated by linearly interpolating from the tables of Van Hamme (1993). Values for the luminosities of the primary stars (normalized to 4π) were calculated assuming both stars had identical effective temperatures using

$$L_i = 4\pi R_i^2 \sigma T^4 \quad (50)$$

and

$$L_1 = 4\pi \frac{L_1}{L_1 + L_2}. \quad (51)$$

Figure 10 - The determination of the relationship between $(V-R)_J$ and $(V-I)_{JC}$.

If an initial difference between the V and I luminosities or between primary and secondary temperatures was used, it resulted from a guess as the models were expected to quickly move to reasonable values. The normalized luminosity of the secondary star is constrained in WD by the values of other parameters and hence is not determined directly by the user. The initial values for Ω were based on values from systems with similar light curves.

The modelling of the W UMa stars was well underway before the Algol-type system was attempted. By then, experience had demonstrated the efficiency of the simplex program such that the lack of detailed spectral information did not pose a great impediment. Rough guesses were made for most of the modelled parameters, except for the primary temperature and semimajor axis, which were estimated as per the contact systems. Convergence to reasonable and self-consistent values occurred after only a few simplex runs.

In all cases the eccentricity and the argument of the periastron were held at zero and 90 degrees, respectively, since no compelling evidence for non-circular orbits was seen. Since the data supplied by Lin Yan and Mario Mateo (private communication) were not phased, the phase shift, $\Delta\phi$, was modelled in all cases. Initial estimates for $\Delta\phi$ was visually estimated from the light curves. For effective temperatures above 6000 K, a radiative atmosphere was assumed and gravity darkening coefficients, g_i , were kept constant at 1.00. For effective temperatures below 6000 K, a convective atmosphere was assumed and gravity darkening coefficients were kept at 0.32 after Lucy (1967). Similarly, albedos, A_i , were held at 1.0 and 0.5 for radiative and convective atmospheres respectively. In some instances where modelled temperatures fluctuated around the 6000 K level, the 6000 K division was not rigidly adhered to until temperature convergence, at

which point the gravity darkening coefficients and albedos were changed appropriately. The initial estimates of all these parameters are summarized in Table 3.

TABLE 3
Initial Estimates for Model Parameters

Parameter	V1	V2	V3	V4	V5
$\log(g_1)$	4.40	4.38	4.31	4.4	4.32
$\log(g_2)$	4.36	4.35	4.23	4.3	4.29
a (R_{sun})	2.49	2.57	2.61	4.97	2.75
$\Delta\phi$	0.50	0.37	0.10	0.80	0.80
i	88°	81°	82°	80°	79°
g_1	0.32	1.00	0.32	1.00	0.32
g_2	0.32	0.32	0.32	0.32	0.32
T_1 (K)	5460	6050	4740	6500	5900
T_2 (K)	5300	6050	4700	5000	5900
A_1	0.50	1.00	0.50	1.00	0.50
A_2	0.50	0.50	0.50	0.50	0.50
Ω_1	2.4	2.6	1.9	3.5	2.5
Ω_2	n/a	n/a	n/a	2.8	n/a
q	0.35	0.44	0.17	0.40	0.42
L_1^{v}	9.03	8.52	10.45	11.00	8.66
L_1^{I}	9.06	8.52	10.45	10.50	8.70
X_1^{bol}	0.521	0.496	0.538	0.5	0.502
X_1^{v}	0.650	0.569	0.765	0.6	0.587
X_1^{I}	0.474	0.411	0.551	0.4	0.425
X_2^{bol}	0.521	0.496	0.538	0.5	0.502
X_2^{v}	0.650	0.569	0.765	0.6	0.587
X_2^{I}	0.473	0.411	0.550	0.4	0.425

Before the modelling could begin, the DC input files had to be constructed. There were several concerns. Firstly, the light curves must be converted from magnitudes to normalized light units. This was done using a spreadsheet program and the equation

$$L = \frac{l_i}{l_{\text{max}}} = 10^{\left(\frac{m_i - m_{\text{max}}}{-2.5}\right)}, \quad (52)$$

where m_{max} is the peak brightness (smallest magnitude) of the light curve. This was determined from the light curve plots by visual inspection. For systems with a clear O'Connell effect⁶, the brighter of the two maxima was used.

Secondly, the weights for the data points and light curves had to be determined. Almost all data points were given weights (between 0 and 99) that were inversely proportional to their photometric errors. A few widely divergent points were given zero weight. If modelling with simplex made it clear that more weight was required for certain points to get an acceptable fit, their weight was increased. Usually it is sufficient to increase weights for this reason only temporarily in order to encourage the location of the best minimum—once the search closes in on the solution the weights for these data points can be restored to their normal values. However, it was discovered that the few points comprising the flat bottom of the secondary minimum of the V1 (Figures 7a and 7b) light curves had to be left at triple values or the programs would converge to light curves that were obviously too shallow in the secondary minimum. Normally it is desirable to avoid the arbitrary adjustment of data point weights, but in this instance, the under-sampling of a crucial part of the light curve hindered the determination of an accurate solution. The few points in the secondary minima (V and I curves) play an unusually important role in constraining the system's parameters, and hence required unusually high weights to obtain reasonable results. The light curves are also weighted, allowing higher quality light curves to play a more important role in determining parameters. For the light curves considered here, the qualities of the V and I light curves were approximately equal and so they were

⁶ Eclipsing binary light curves which exhibit the O'Connell effect have maxima of differing brightnesses. This difference may be due to star spots being distributed unevenly over the stars' surfaces (Davidge & Milone, 1984).

given equal weight, except in the case of V2, which had far fewer points in the I light curve. For this reason, the I light curve was given less weight than the V curve.

Finally, there are several factors related to the operation of the programs. The increments applied to the parameters during partial derivative approximations in WD are set in the first three lines of the standard DC input file. They are also contained in the simplex input file but are obviously not used since simplex does not require partial derivatives. The values used were not changed. The number of grid points into which the model stars are divided is also adjustable. The *grid size integers* are specified for both high and low precision calculations, the latter applying to certain derivatives requiring less precision in order to save computation time. Specifically, these numbers determine the number of latitude rows per hemisphere. The number of longitude rows is scaled with the number of latitude rows and with the approximate sine of the latitude. The selected high and low precision grid size integers were 30 and 15, respectively, for both stars.

Once the input files were constructed, the modelling could begin. The general procedure was to perform several simplex runs starting at or near the region of parameter space suggested by the initial estimates. The final location for the converged simplex (*i.e.*, the average of the vertices of the final simplex) was then used as the starting place of a new run if the fit corresponding to that location in parameter space was comparable (within $\Delta\sigma \approx 0.015$) to the best runs up to that point. This process was repeated for each promising simplex location until the final location of the simplex did not migrate from run to run. Generally, no more than three runs were required to meet this condition. At this point, if more than one minimum had been found, it was clear which was the best and fine-tuning with WD could begin. To this end, several iterations of DC were applied until it became clear that either the best minimum had been found or that further searching was required. If convergence seemed to be not imminent in the WD fine-tuning, further

simplex runs were employed, often beginning with parameters suggested by the main WD correction set. This proved often to be a successful strategy. For parameters that generally are not strongly determined, such as inclination, several simplex runs were started with a range of values to search for better values that might not otherwise be found due to very shallow gradients along those axes in parameter space. Thus the simplex routine provided a useful tool both for establishing the current region of parameter space and for exploring alternative regions. In all, combined operations for all stars required over 100 simplex runs and well over 600 DC iterations.

5.0 RESULTS AND DISCUSSION

The best fit solutions for atmosphere flux ratios with $[\text{Fe}/\text{H}] = -0.3$, -0.5 , and -1.0 were found for each of the binary systems. The two measures used to gauge the goodness-of-fit of the light curve data are the sum of the weighted residuals squared (Σwr^2) and the standard error of a single average weighted point (σ). The best fit (smallest Σwr^2 or σ) was usually obtained with the $[\text{Fe}/\text{H}] = -0.3$ models but the significance of this should not be overestimated. The modelling was initially done using $[\text{Fe}/\text{H}] = -0.3$ stellar atmospheres and once the solution had been found or nearly found, the other metallicities were tested. Usually only a few iterations were required to converge to an acceptable solution for the other metallicities, although in some cases further exploration was conducted. Therefore, the $[\text{Fe}/\text{H}] = -0.5$ and -1.0 models may not be as optimized as the first model attempted. The best-fit model light curves are shown with the observed light curves (in normalized light units) in Figures 11a through 11j. The small differences in the final solutions due to different metallicities is not large enough to produce discernibly different light curves and so only one set of V and I curves per system is shown. The predicted radial velocity curves are also included (Figures 12a through 12e) as an aid to, and test of, future observations. Using the modelling results, the absolute parameters of each system were calculated as follows.

While the semi-major axes are listed as model parameters, they in fact play a very small role in models of systems for which radial velocity data are not available. All parameters that are dependent on the scale of the system, such as the radii, are expressed in units of the semi-major axis. Consequently, any change to the semi-major axis of a model will affect the light curves only by virtue of slight changes in the limb darkening coefficients and model atmosphere flux, which are surface gravity dependent. It is

therefore justifiable to adjust the semi-major axes to allow for more appropriate masses and not expect significantly different light curve solutions. As described, the values of the semi-major axis used in the models were calculated on the assumption that the total mass was equal to 1.7 solar masses. Better information did not become available until after the modelling was nearly complete. Based on the positions of the binary systems on the M71 colour magnitude diagram, Yan & Mateo (1994) gave approximations for the total masses. They assumed the total mass of each system, M_{tot} , to fall between M_{MS} and M_{max} , where M_{MS} is the mass of a single star in M71 that has the same luminosity as the binary, and

$$M_{\text{max}} = M_{\text{MS}}(1 + q). \quad (53)$$

In this equation, the mass ratio, q , is assumed to be less than one. Their estimates of q , based on the Fourier analysis described by Rucinski (1993), have now been improved through modelling and the total mass estimates were changed accordingly.

While the semi-major axis is not required for light curve modelling, it is crucial to the calculation of absolute parameters. Using the new mass estimates (M was taken to be the mid-point between M_{MS} and M_{max} and ΔM was taken to be half the difference between the extremes), a was calculated for each of the systems using equation (4). These values of a were then used to find the effective radii, R_{eff} , of each binary component:

$$R_{\text{eff}} = \left(\frac{S}{4\pi} \right)^{1/2}, \quad (54)$$

where S is the surface area calculated and printed out by WD in units of α^2 . The bolometric luminosity, L_{bol} , of each component was then calculated from

$$L_{\text{bol}} = 4\pi R_{\text{eff}}^2 \sigma T^4. \quad (55)$$

The absolute bolometric magnitude of each component was then calculated by means of the expression

$$M_{\text{bol}} = M_{\odot}^{\text{bol}} - 2.5 \cdot \log\left(\frac{L_{\text{bol}}}{L_{\odot}}\right), \quad (56)$$

where M_{\odot}^{bol} was taken to be 4.76 (Mihalas & Binney 1981). Using bolometric corrections based on the models of Vandenberg & Bell (1985), the absolute visual magnitudes were then found. An uncertainty in the bolometric corrections of 0.05 was assumed based on an uncertainty of 150 K for each effective temperature. The combined absolute visual magnitudes were then found from:

$$M_{\text{both}}^V = M_1^V - 2.5 \cdot \log\left(1 + 10^{\left(\frac{M_2^V - M_1^V}{-2.5}\right)}\right). \quad (57)$$

The distance moduli (DM) were then calculated. No uncertainty in the reddening-removed magnitudes were specified by Yan & Mateo (1994). Therefore, ΔV_{O} , the uncertainty in V_{O} , was calculated to be 0^m.165 from the expression

$$\Delta V_{\text{O}} = \sqrt{(\Delta V)^2 + (R_V \cdot \Delta E_{(\text{B-V})})^2 + (E_{(\text{B-V})} \cdot \Delta R_V)^2}, \quad (58)$$

where it was assumed that $\Delta V=0.05$, $E_{(\text{B-V})}=0.28 \pm 0.05$ and $R_V=3.1 \pm 0.1$ (Cardelli *et al.* 1989). In all cases, the different metallicity models were not different enough to affect the calculations of absolute parameters, given the reported uncertainties.

The individual components of the binary systems were placed on the CMD of Hodder *et al.* (1992) (see Figure 13). The $(\text{B-V})_{\text{O}}$ values were found using the effective temperatures of the components and the models of Vandenberg & Bell (1985). An uncertainty of 0.06 was assumed based on the 150 K uncertainty in the effective temperatures. Combined with an uncertainty of 0.05 in the colour excess (needed because the Hodder *et al.* CMD is not corrected for reddening), the total uncertainty in (B-V) is 0.08. Combining the uncertainties in M_V , DM, R_V , and $E_{(\text{B-V})}$ gave a net uncertainty in V of roughly 0.29. These errors are clearly quite large, especially in the (B-V) direction.

Figure 13 - The uncorrected colour magnitude diagram of M71 using data from Hodder *et al.* (1992). The isochrones are those of Bergbusch & Vandenberg (1992). The positions of the systems and the individual components of each of the systems are indicated. The filled symbols represent the unresolved binary systems. The empty symbols represent the primary and secondary components of the binary systems—the primary being the brighter of the two components. The cross represents the estimated error in the positions of the components. To place the isochrones on the diagram, an additional shift of 0.015 was added to B-V values, as suggested by Hodder *et al.* (1992)

Improvements to the precision of $E_{(B-V)}$ and the $(B-V)_0$ values would greatly reduce this error. The former may be difficult to improve but the latter would be helped significantly with the aid of spectral information.

5.1 V1, V2, and V5

Of the four binaries suspected of being contact systems, only three proved to be in contact. The parameter sets for the best fit solutions with stellar atmosphere flux ratios of $[Fe/H]=-0.3$, -0.5 , and -1.0 for these three systems are given in Tables 4a through 4c. The other W UMa-type system, V3, is most likely a detached system. Of the three, V1 required the addition of a cool spot on the hotter component in order to obtain a satisfactory fit (see Table 5). The reason for this is the fairly obvious O'Connell effect exhibited in the light curves. Semi-detached models were also investigated with simplex but did not fit the observations as well as the contact models. The model radii and surface areas calculated by WD for the contact systems are given in Tables 6a through 6c. The absolute parameters and related quantities for these systems are given in Table 7. Three dimensional representations of the contact systems are shown in Figures 14a through 14c and their Roche lobe configurations are shown in Figure 15.

Using the mass ranges discussed above (see Table 7), the distances to the three systems were calculated. The results for V1, V2, and V5 are 3.99 ± 0.42 kpc, 3.68 ± 0.35 kpc, and 3.57 ± 0.38 kpc respectively. All are comparable with Richer & Fahlman's (1988) 3.6 ± 0.5 kpc.

The positions of the individual components of the contact systems on the M71 CMD can be seen in Figure 13. All of the components, with the exception of the

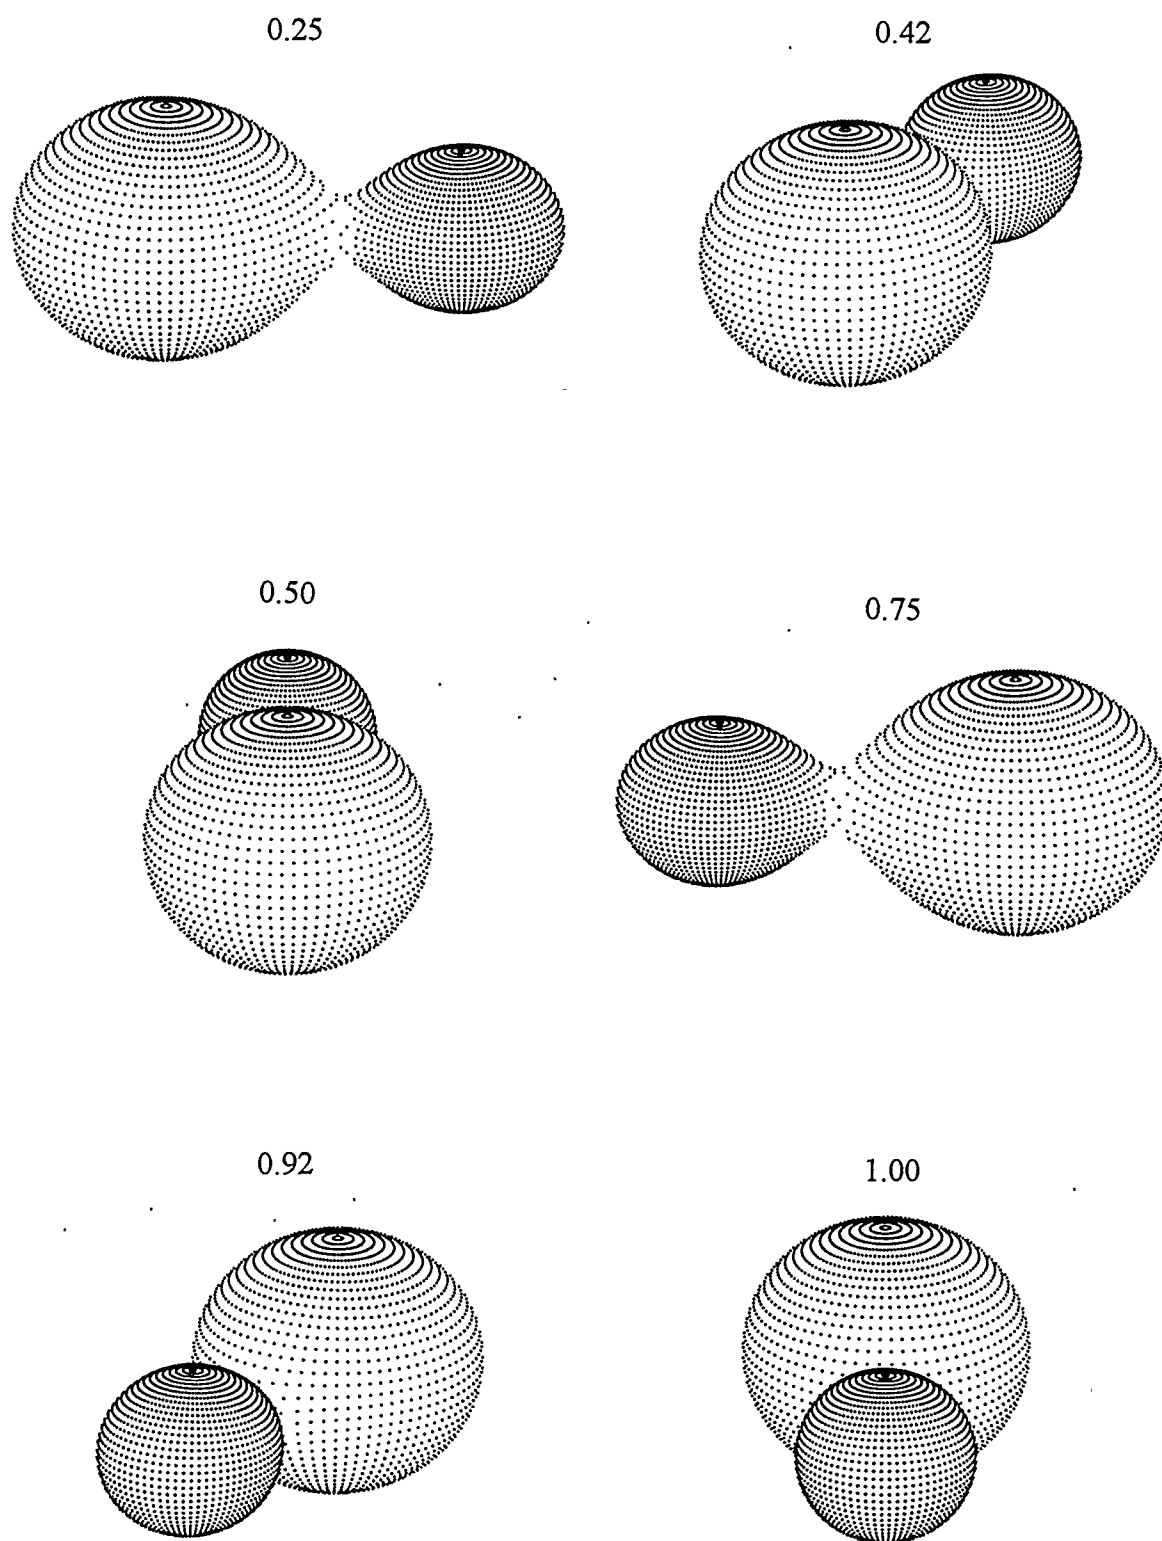

Figure 14c - Three-dimensional representation of the V5 system (see Table 4c for model parameters). The phases represented by each picture are indicated.

Figure 15 - The Roche lobe configurations of V1, V2, and V5, produced with D. H. Bradstreet's *Binary Maker II*. The less massive star is on the left.

secondary star of V5 are quite close to the main sequence. The primaries are roughly 1.5-2.0 magnitudes brighter than their lower mass companions. They are also consistently bluer than their companions, although none of them is sufficiently blue to be conclusively classified as a blue straggler given the uncertainty of these determinations. Two of the systems (V1 and V5) have their primary components located above the main sequence while their companions are both found below the main sequence. This fact suggests the possibility that the more massive stars acquired mass and luminosity from their companions.

It is interesting to compare these binaries with those found in NGC 5466 by Mateo *et al.* (1990) and modelled by Kallrath *et al.* (1992). In that case, the two contact systems were found to be blue stragglers. Of the M71 contact systems, before being resolved into individual stars, V2 and V5 are very near the main sequence, and V1 is *redward* of the main sequence. This is not surprising given the state of contact of the systems. Kallrath *et al.* found the outer critical surfaces to be nearly filled by the stars, their fill-out factors both being equal to ~ 0.95 . The present work shows V1, V2, and V5 to have fill-out factors of 0.15, 0.06, and 0.27 respectively. The M71 systems are only slightly in contact so that their degree of mutual influence is not expected to be as high as in the case of the NGC 5466 contact binaries.

Rucinski (1994) has proposed that W UMa might be used as standard candles for distance determinations. He has found an empirical relationship between period, colour, and luminosity. Based on B-V colours he finds a linear relation of the form

$$\begin{aligned}
 a_{P(BV)} \log P + a_{BV} (B - V) + a_{0(BV)} &= M_V \\
 a_{P(BV)} &= -2.44^{+0.70}_{-1.50} \\
 a_{BV} &= +4.20^{+0.29}_{-0.68} \\
 a_{0(BV)} &= +0.23^{+0.30}_{-0.28}
 \end{aligned} \tag{59}$$

This relation can be tested for the M71 contact systems. The periods and V magnitudes from Table 2b were used, along with $(B-V)_0$ values found from the models of Vandenberg (1985), to find the distance moduli of the three binaries. In determining the uncertainty in DM, the values of the coefficients in equation (59) were chosen such that the maximum range was achieved. The values were found to be 13.69 (+1.01, -1.16), 13.91 (+0.89, -1.09), and 13.92 (+0.90, -1.03) for V1, V2, and V5 respectively. As can be seen from Table 9, the agreement between these values and those derived in the present work is quite poor. Only the two determinations for V1 fell within each other's uncertainty range. However, the fact that the Rucinski values are consistently higher than those listed in Table 9 implies a systematic error possibly due to the transformation between V-I and B-V. Rucinski also determines a relationship using V-I colours:

$$\begin{aligned}
 a_{P(VI)} \log P + a_{VI}(V - I_C) + a_{0(VI)} &= M_V \\
 a_{P(VI)} &= -4.28^{+1.30}_{-2.84} \\
 a_{VI} &= +3.67^{+0.63}_{-1.27} \\
 a_{0(VI)} &= -0.37^{+0.38}_{-0.35}
 \end{aligned} \tag{60}$$

If this relationship is used to avoid the colour transformation, the results are in better agreement with the DM determined through modelling: 13.23 (+4.62, -2.16), 13.41 (+4.28, -2.00), and 13.52 (+4.03, -1.90) for V1, V2, and V5 respectively. Obviously, this relationship suffers from an even greater lack of precision than the B-V relationship. This is due to the very small sample size used for its determination: only 3 binaries with V-I colours were available; the rest of the sample was composed of half-weighted systems with V-I colours transformed from B-V values. The three M71 contact systems studied here will, therefore, be a valuable addition to the V-I sample. When the reduction of the 5-colour Mt. Laguna CCD frames is completed, these stars will also supplement the relatively small (less than 20) B-V sample.

The origin of these stars is also of interest. Do the binaries represent the result of collisions? This possibility cannot be ruled out but M71's age is sufficient for merger hypotheses to be important competitors. The magnetic braking theory of contact system formation predicts that considerable time is required to bring initially detached components into contact. Vilhu (1982), for instance, estimates that two 1 solar mass stars with an initial period of 4 days will come into contact in $\sim 10^{10}$ years. In young clusters, therefore, it can be argued that contact systems must be caused by some other mechanism. This argument cannot be applied to M71 because of its large age. However, one might ask if binary systems could survive the effects of collisions over the time interval required for them to come into contact. This question is considered by Yan & Mateo (1994) who find the timescale required to destroy binaries with periods less than 2.5-5 days and component masses of 0.7 solar masses exceeds 10^{11} years. Binary-binary interactions are expected to be more common because the interaction cross-section increases as the semi-major axis, but interactions with large period, low orbital velocity binaries will tend to harden binaries rather than destroy them (Hills 1990).

It is also possible that the binary systems discussed here were produced through binary-binary interactions but Yan & Mateo (1994) argue against this scenario. Adapting the work of Leonard & Fahlman (1991), they conclude that only 3-4 short-period binaries are expected to be created during wide-binary interactions in M71, assuming that the maximum stable orbital period in M71 is ~ 800 years (Hills 1984). Contact binaries are expected to merge completely from the time of initial contact within $\sim 5 \times 10^8$ years (Stryker 1993). This would imply that all of the short-period binaries expected to be formed in this manner were formed within a small fraction of the M71's lifetime. While not impossible, assuming that the figures of Yan & Mateo are accurate, it seems unlikely that more than one, if any, of the contact binaries observed in M71 were formed in this fashion.

The origin of the M71 contact systems may be in question but their ultimate fate is fairly certain: within $\sim 10^9$ years, these stars will have merged. Whether they will become blue stragglers depends on the mass of the merged star. If it exceeds the turn-off mass of the cluster, the recently-formed 'high' mass star will appear above and blueward of the other cluster members on the main sequence. Merged stars of mass less than the turn-off mass will move up the main sequence but remain among other stars of comparable mass. These stars will form *latent blue stragglers*, being exposed after the stars near them on the CMD evolve off the main sequence. The precise fate of the M71 contact systems, therefore, obviously depends largely on their current mass. Also, their final, merged mass may be affected by mass loss during the merger process. As the stars of a binary system merge, the Roche lobes become increasingly small. If the outer critical surface of the system can no longer contain the stars, material will be lost from the system. The NGC 5466 contact systems, which are very close to filling their outer critical surfaces, may have already lost mass and could represent the fate of the M71 contact systems as they merge further. A quantitative investigation of how these systems fit into current binary star evolutionary models is beyond the scope of the present work but would be an interesting subject of future study.

5.2 V4

Three models of V4, the Algol-type system, were produced. The initial model, which has the lowest $\Sigma w r^2$, is a detached system with the secondary star smaller than the primary star so that the primary eclipse is a transit eclipse. The secondary star in this model is close to filling its Roche lobe ($f = -0.11$). Because of this, the possibility of a semi-detached system in which the secondary star fills its Roche lobe was also investigated.

The Σwr^2 of this model was not as small as that of the detached system (0.262 as compared to 0.257). This result was expected as the potentials Ω_i of the two stars in the initial detached model were not constrained and the secondary potential would be expected to migrate to a smaller value, had the semi-detached system been more desirable. Careful spectroscopy or infrared photometry could reveal the existence of circumstellar matter, which would lend support to the semi-detached model in which the secondary star is slowly losing mass to form an accretion disk around its companion. However, in the absence of such evidence, the detached model is the more likely of the two. A third model investigated was for the case in which the primary star is the smaller of the two, meaning that the primary eclipse is an occultation eclipse. The fit of this model to the observed light curve was the worst of the three models ($\Sigma wr^2=0.264$). The model parameters for each of these models are given in Tables 8 and 9. The radii and surface areas calculated by the WD program for the three models are given in Tables 10 and 11. The absolute parameters and related quantities for the models are given in Table 12. Three dimensional representations of the models are shown in Figures 16a through 16c and their Roche lobe configurations are shown in Figure 17.

The calculated distances (using the assumed mass ranges discussed earlier and given in Table 10) for the two transit case models were 3.33 ± 0.39 kpc (detached) and 3.32 ± 0.42 kpc (semi-detached), both in agreement with the Richer & Fahlman (1988) distance for M71 of 3.6 ± 0.5 kpc. The occultation model implies a distance 3.03 ± 0.36 kpc and so V4 would be less likely to be a cluster member if it were accurately represented by this model. The fact that the better models (smaller Σwr^2 and σ) indicate cluster membership lends weight to V4 being a cluster member.

The positions of the detached model components on the M71 CMD of Hodder *et al.* (1992) are shown in Figure 13. The primary is slightly blueward of the main sequence near the turn-off but there is considerable uncertainty in V and $B-V$. The secondary component is redward of the main sequence and just fainter than 20^{th} magnitude. The fact

that the primary component is near the main sequence and slightly fainter than the turn off magnitude is interesting because it may provide an observationally determined limit to the turn-off mass of M71. However, the displacement of the stars from the main sequence may imply that the evolution of the two components was influenced by mass exchange. Considering how close the secondary component is to filling its Roche lobe, this is not an unreasonable concern. To test this hypothesis, evolutionary models must be consulted.

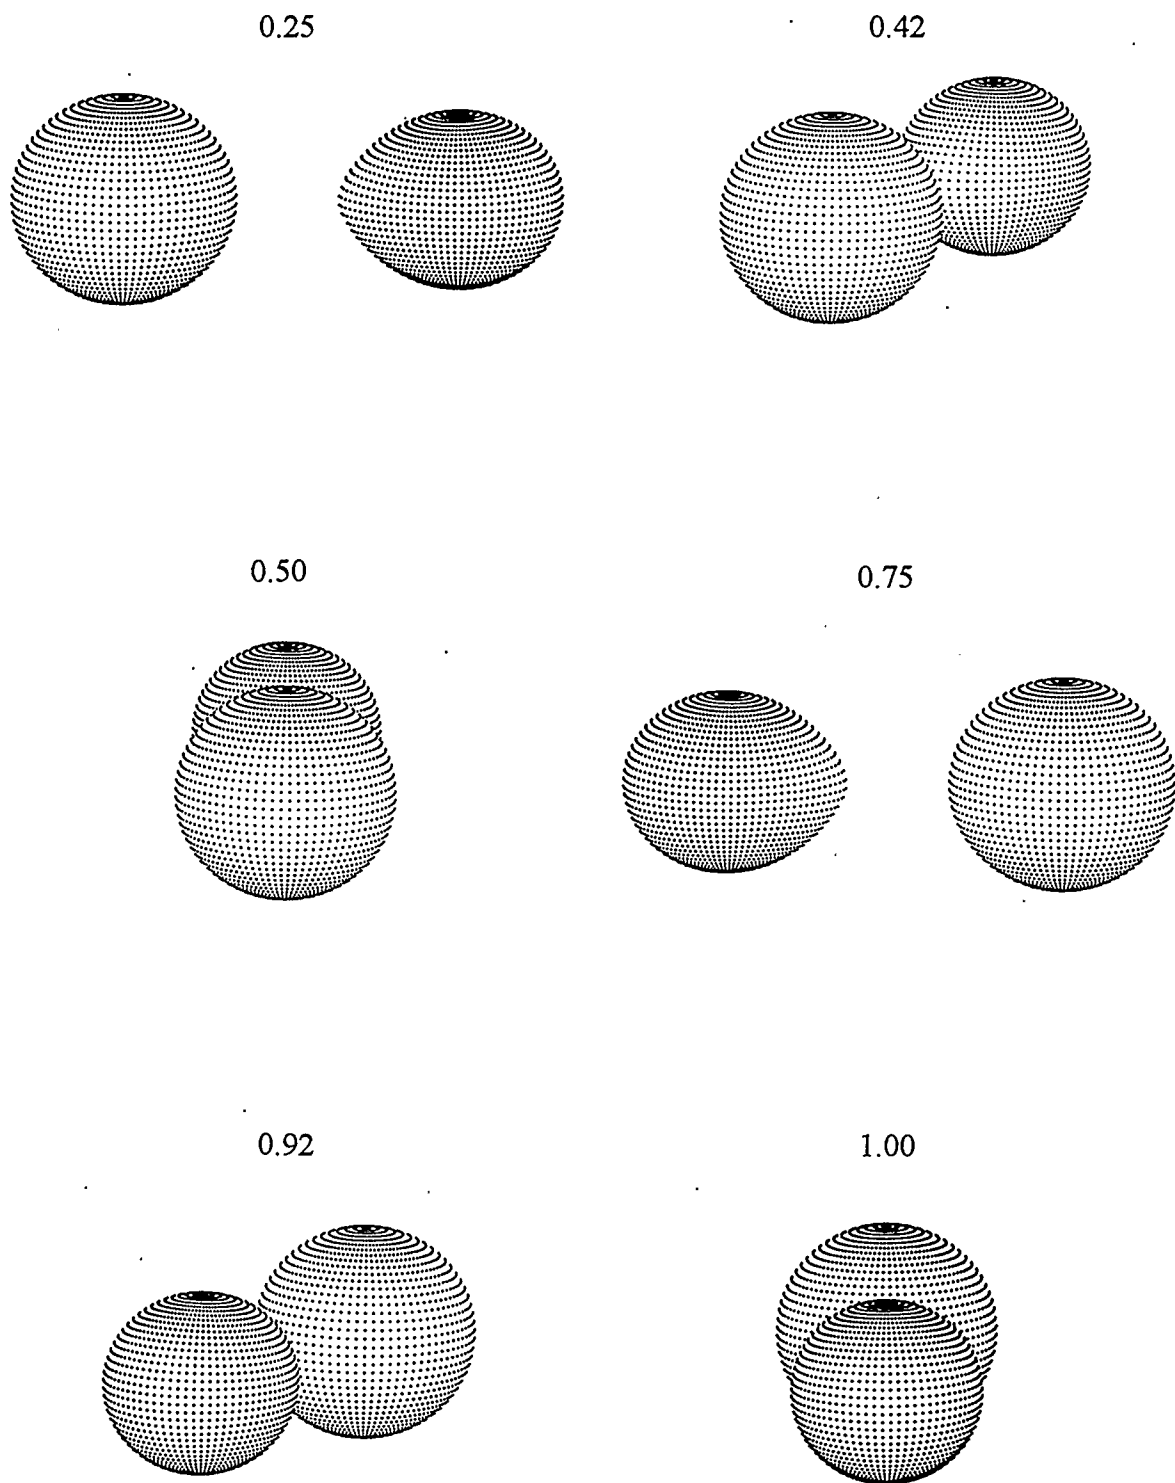

Figure 16a - Three-dimensional representation of the V4 system (see Table 8 for model parameters). The phases represented by each picture are indicated.

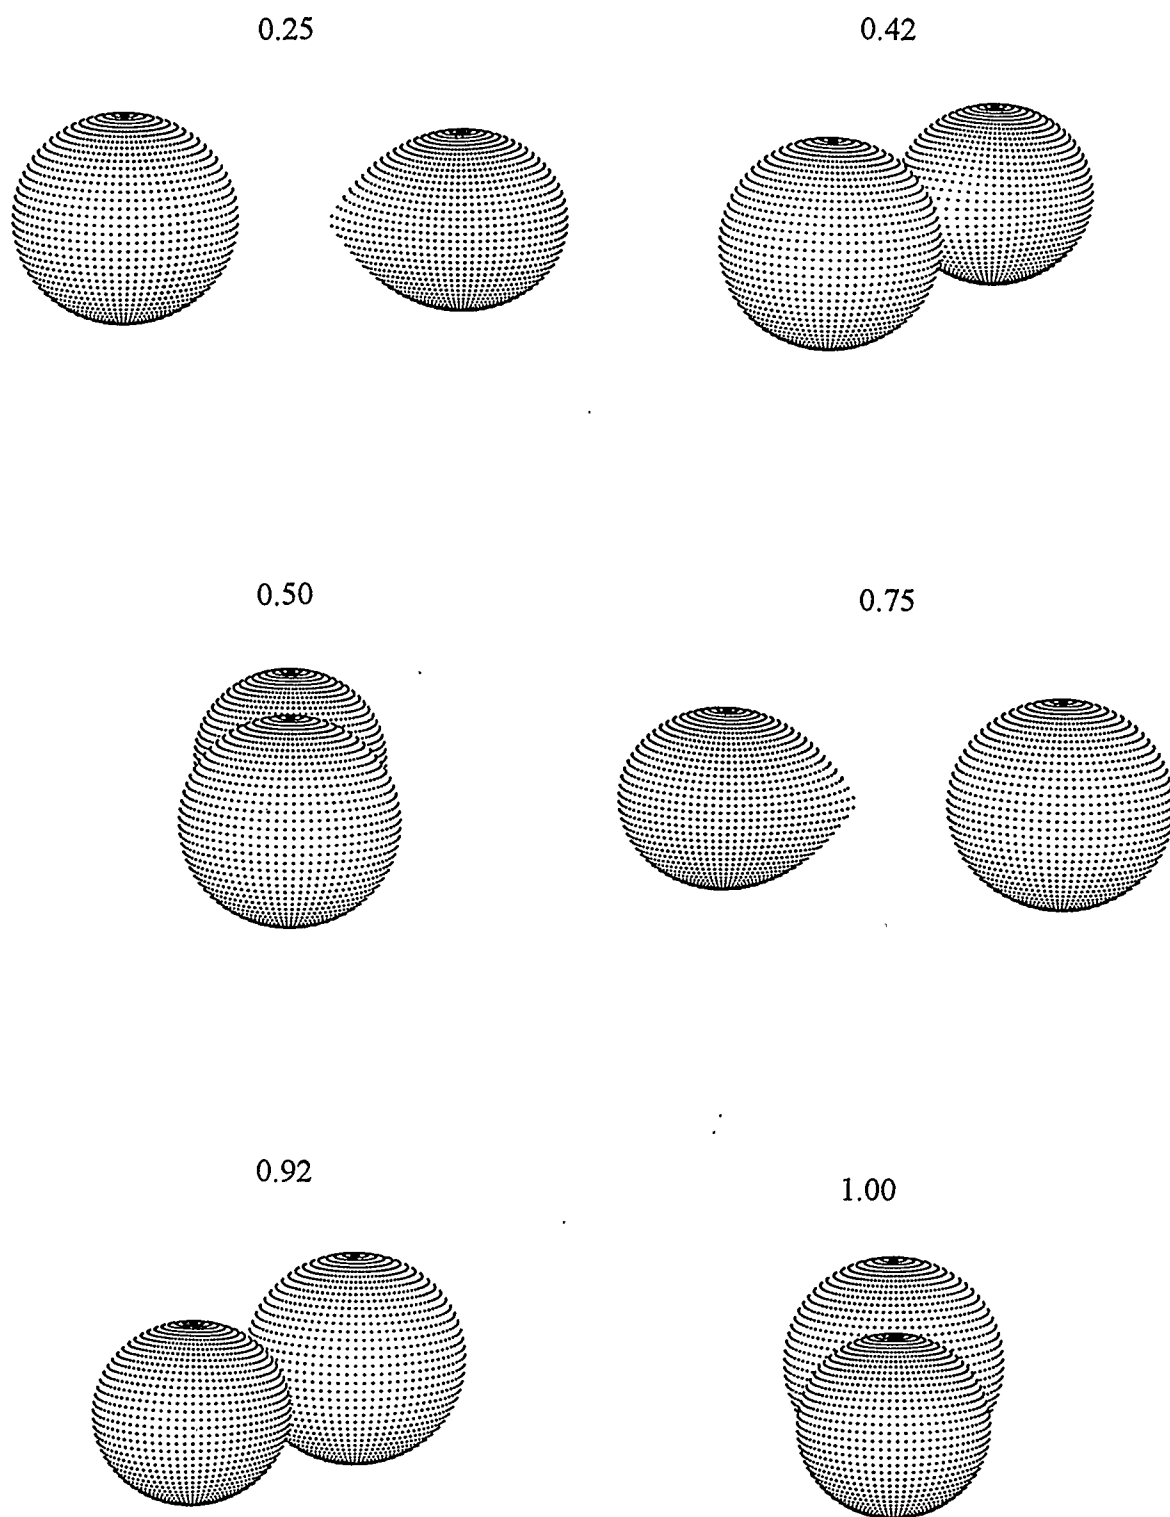

Figure 16b - Three dimensional representation of the semi-detached model of V4 (see Table 9 for model parameters). The phases represented by each picture are indicated.

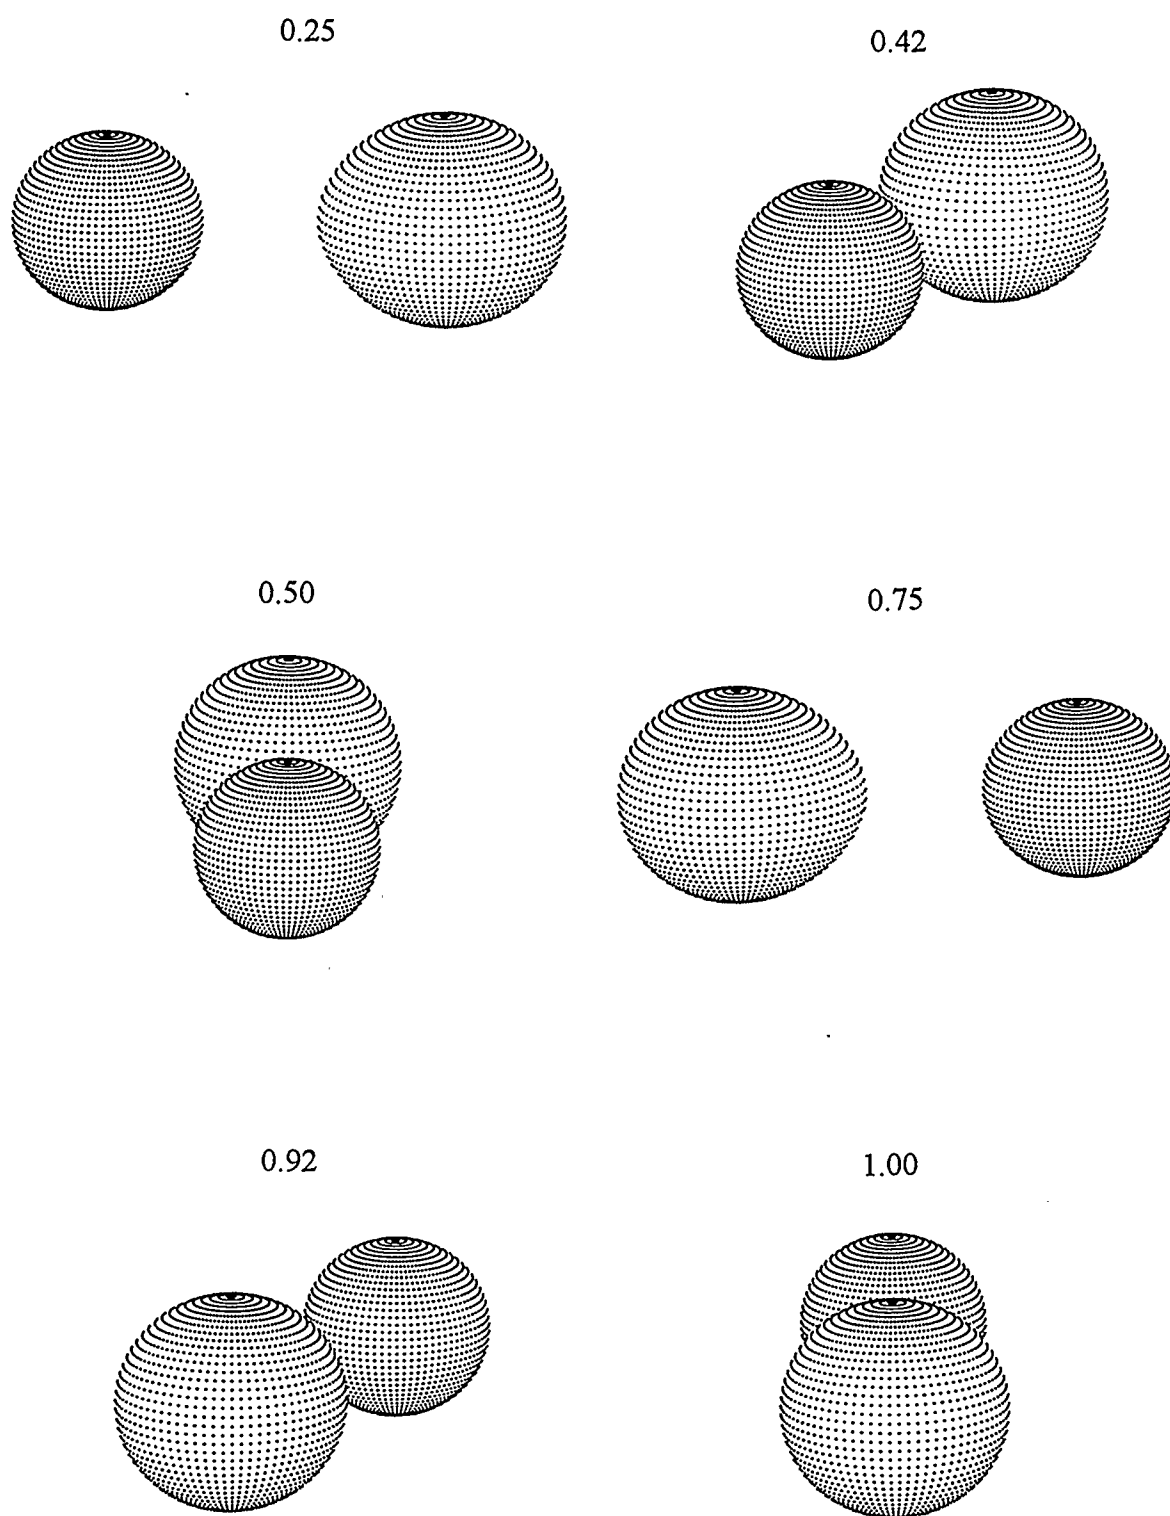

Figure 16c - Three dimensional representation of the occultation model of V4 (see Table 9 for model parameters). The phases represented by each picture are indicated.

Figure 17 - The Roche lobe configurations of the V4 models (adopted, semi-detached, and occultation from top to bottom). The less massive star is on the left.

The evolutionary tracks of VandenBerg & Bell⁷ indicate that a 0.6 solar mass star (the detached model predicts a primary mass of 0.61 ± 0.11 solar masses) would not have exceeded its current size since it moved on to the main sequence within the lifetime of M71. Therefore, it is not expected to have filled its Roche lobe in the past since it does not currently. This assumes $Y=0.2$ and $Z=0.006$. Even under the more unfavorable circumstances of a 0.7 solar mass star with $Z=0.003$ (since lower metallicity stars evolve at a greater rate), the star is not expected to have exceeded its current size in the past. The same argument can be made for the less massive star (0.23 ± 0.04 solar masses) since its main sequence lifetime is expected to be much longer.

This represents the most obvious scenario and makes V4 very similar to DS And (Schiller & Milone 1988), which also has its primary component near the cluster turn-off and its secondary component, which nearly fills its Roche lobe, somewhat redward of the main sequence.

It is, however, possible to argue that if the stars have exchanged mass in the past, the masses of the components could have been significantly different than they currently are, meaning that the above argument is not valid. Suppose the system had a fairly extreme initial mass ratio of 0.15. This mass ratio would imply a primary component of mass 0.87 solar masses, assuming that the upper end of V4's assumed total mass range is adopted, *i.e.*, 1.0 solar mass. Such a star will evolve faster than the 0.61 solar mass star considered above. In order to determine how long it would take for this hypothetical star to start transferring mass to its companion, the size of the corresponding hypothetical

⁷ Single star evolutionary tracks are consulted because, up until the time that binaries exchange mass, the components are assumed to evolve in the same manner as single stars, although it is likely that the proximity of the stars actually affects their evolution to an extent that has not yet been clearly established.

Roche lobe must be calculated. Using equation (46), the effective radius of the Roche lobe of the primary component of a binary system with $q=0.15$ was found to be $0.5451 \cdot a$. The semi-major axis is affected by mass transfer and must be calculated for this ‘primordial’ mass ratio.

The total angular momentum of a binary system, J , can be expressed as

$$J = M_1 a_1^2 \omega + M_2 a_2^2 \omega + I_1 \omega_1 + I_2 \omega_2, \quad (61)$$

where a_1 and a_2 are the same as in equation (4), I_1 and I_2 are the moments of inertia of the two stars, ω_1 and ω_2 are the angular rotation rates of the stars, and ω is the angular orbital revolution rate. Assuming that the stars are centrally condensed, and hence that the stellar moments of inertia are negligible, the equation can be simplified:

$$J_{orb} = \frac{M_1 M_2}{M_1 + M_2} a^2 \frac{2\pi}{P}. \quad (62)$$

Combining this with equation (4) gives:

$$J_{orb} = G^{1/2} \frac{M_1 M_2}{(M_1 + M_2)^{1/2}} a^{1/2} \quad (63)$$

If mass exchange conserves angular momentum and total mass, then the current angular momentum should be equal to the primordial angular momentum. Equating the two and simplifying gives:

$$a' (M_1' M_2')^2 = a (M_1 M_2)^2, \quad (64)$$

where the primed quantities refer to the primordial system. So if the primordial mass ratio q' was 0.15, then $a' = 3.06 \cdot a$. Using a value of a appropriate for a 1.0 solar mass system yields $a' = 8.71$ solar radii. Therefore, the Roche lobe of this hypothetical primordial system would have had an effective radius of 4.75 solar radii. The isochrones of Bergbusch and Vandenberg (1992) indicate that a 0.87 solar mass star with a metallicity

in the range of $[\text{Fe}/\text{H}]=-0.47$ to -0.78 will not exceed this size in 14 Gyr. However, in 16 Gyr, 0.87 solar mass stars with $[\text{Fe}/\text{H}]=-0.65$ and -0.78 will exceed this size, while a $[\text{Fe}/\text{H}]=-0.47$ star will not. It should be noted that the assumption that angular momentum is conserved represents a worst-case scenario for the argument that mass has not been exchanged. If the mass exchange does not conserve angular momentum, the primordial semimajor axis would be even larger, strengthening the case for there having been no past mass exchange. In conclusion, the precise values for M71's age and metallicity are crucial in determining if mass transfer could have taken place in the V4 system. Considering the uncertainties in the age⁸ and metallicity of M71, and the mass of the V4 system, mass transfer in V4's past cannot be ruled out by this argument.

Is it likely that the mass ratio could have changed from 0.15 to its current 0.376? This question would be logically addressed by consulting binary star evolutionary models (reviews of this topic can be found in Paczynski 1971, Thomas 1979, and Iben, 1991 for example). As was noted above, the evolutionary status of V4 is very sensitive to mass, mass ratio, metallicity, and separation—small changes in any of these quantities are enough to significantly affect conclusions concerning V4's status. Unfortunately, the author was unable to locate binary star evolutionary models that are suited to the

⁸ Demarque *et al.* (1992) argue that most isochrones calibrated with the same observational data will give approximately the same ages. In particular, mixing lengths for isochrones of near solar metallicities must be chosen to reproduce the radius of the Sun. Ages derived from inappropriately calibrated isochrones will not be accurate. For instance, estimates of the age of NGC 6791 based on Vandenberg's (1985) isochrones are too old by ~ 4 Gyr. Based on these isochrone, the Sun would have an age of greater than ~ 8 -10 Gyr. Vandenberg (1992) claims that until globular cluster distance estimates are refined, age uncertainties of ~ 3 Gyr will persist.

hypothetical primordial V4 system. When suitable binary star evolutionary models become available, the question of the likelihood of a change in V4's mass ratio from 0.15 to 0.376 can be investigated by this means. Until then, the question must be addressed less directly.

If the more massive component of a binary system loses mass to its companion, its Roche lobe will contract. This can lead to runaway mass transfer if the rate of contraction for the star due to mass loss is not as great as the Roche lobe contraction rate. Under these circumstances, mass loss will occur on a dynamical timescale, τ_d . Such a timescale is a measure of the time required for the system's motions representing its response to an arbitrary disturbance (Kopal, 1978) and is given by

$$\tau_d \approx \left(\frac{R^3}{GM} \right)^{1/2}. \quad (65)$$

A second possibility is that as the star loses mass, it cannot remain in thermal equilibrium and contracts to just within its Roche lobe. In this case mass loss will proceed on a thermal timescale, τ_{th} , the time needed for the system to contract from infinity to the current form, which is given by

$$\tau_{th} \approx \frac{GM^2}{RL}, \quad (66)$$

where L is the luminosity of the system (Kopal, 1978). The ability of a star to contract rapidly enough to avoid an exponential increase in mass loss rate as its Roche lobe contracts depends on its thermal structure. Specifically, stars with radiative envelopes will respond to initial mass loss by rapidly contracting. Conversely, stars with convective envelopes may expand as a result of mass loss and tend to be unstable to dynamical timescale mass loss (Webbink 1985).

The proposed hypothetical star of mass 0.87 solar masses will have a convective envelope when it reaches a size large enough to fill its Roche lobe (Webbink 1985) and so dynamical mass loss would be expected to occur. Mass would be lost by the primary component very quickly, possibly faster than its accreting companion could accommodate, thereby causing mass to be lost from the system if the mass loss rate was sufficiently large. The mass loss would halt only after the primary star's Roche lobe stopped its rapid contraction or when the star became capable of remaining within its Roche lobe. The former circumstance would only occur after the system's mass ratio slightly exceeded unity. The latter circumstance would most likely result in mass exchange proceeding on a slower thermal timescale. In either of these cases, mass exchange would be expected to proceed past mass equalization before halting. Since the current mass ratio of V4 is only 0.376, it seems reasonable to conclude that mass exchange probably did not occur in the past.

A caveat is necessary, however, since binary star evolution is still not well understood. All of the uncertainties that limit single star evolution studies apply to binary stars, and additional problems make matters much more complicated: tidal distortion for close binaries means models must be three-dimensional rather than one-dimensional; tidal effects may cause currents that cannot be dealt with in normal evolutionary models; tidal heating may be significant; mass transfer and/or loss, which is very sensitive to the structure of the stars; non-conservation of angular momentum; physical processes such as turbulent viscosity and meteorological phenomena such as electrodynamical storms that may result from mass transfer but for which we do not yet have quantitative descriptions; and potentially many other complications that are not normally considered for single star evolution (Iben 1991). Given these complications and the fact that even models that do not consider many of these complications predict very complicated evolutionary paths for

binary systems (see Iben & Tutukov (1985) for some well-annotated examples of binary evolutionary tracks), caution is required before making firm conclusions about the V4 system.

The displacement of the V4 secondary component from the CMD main sequence is problematic for the hypothesis that mass exchange has not occurred, although the width of the main sequence and the uncertainty in the secondary's position determination still allow that the secondary could be a normal main sequence object. The model radii of the V4 components are also problematic. The ratio of the radii of the V4 components is expected to be ~ 2.5 (Milhalas & Binney 1981) if the stars were main sequence objects while the adopted model indicates a ratio of ~ 1 . How can this observation be consistent with the argument that mass exchange has not taken place because the current mass ratio of V4 is unlikely if mass exchange had occurred? Lucy (1976) has proposed that contact binaries go through short-lived intervals during which the contact between the stars is broken. During these intervals, the system assumes a semi-detached configuration. XZ Canis Minoris is possibly an example of such a system (Terrell *et al.* 1994) and is very similar to V4 in many respects, including mass ratio. However, given that such broken-contact systems are expected to be difficult to observe due to the fact that the duration of the broken-contact interval is only of the order of 10^6 years, and that the preferred model for V4 is not semi-detached, there are some problems with this evolutionary interpretation of V4.

In conclusion, the evolutionary status of V4 is unsettled. If mass exchange has occurred, then, as was the case for the contact systems, it will be interesting to see how V4 fits into current binary star evolutionary models. On the other hand, if mass exchange has not occurred, V4 could provide important checks for single star evolutionary models.

The resolution of this question will certainly be accelerated by the acquisition of spectral information.

5.3 V3

The best-fit model of V3 indicates that it is a detached system. The parameters for this model are given in Table 13. Because the light curves exhibit a strong O'Connell effect, they were modelled with a single cool spot in the primary component (see Table 14). The radii and surface areas of the V3 stars are given in Table 15. The absolute parameters and related quantities for this system are given in Table 16. A three dimensional representation and the Roche lobe configuration for the system are given in Figures 18 and 19.

If V3 is a member of M71, it is potentially of interest for the same reasons as V4. In this case though, the small mass ratio of V3 implies that it is less likely that the primary star is unevolved. With a calculated mass of 0.80 ± 0.08 solar masses, arguments concerning changes in mass ratio are not required for the primary component to exceed the current turn-off mass of M71 (based on Bergbusch and Vandenberg (1992) models).

The location of the individual components of V3 on the CMD is suggestive of mass and luminosity being gained by the more massive component at the expense of its companion, as was the case for V1 and V5. Again, this is only true if V3 is a member of M71.

Unfortunately, the calculated absolute parameters for this system suggest that it is not a member of M71. The derived distance of V3 (3.17 ± 0.35 kpc) make the membership of this system the least likely of the five binaries. Yan and Mateo (1994) also found this star to be the most likely non-member, because of its position on the CMD. The

individual components of V3 have been placed on M71's CMD (see Figure 13) assuming a reddening value appropriate for cluster membership. Of all of the binaries, V3 is the only system to have its primary located significantly off the main sequence. While not precluded by these observations, the cluster membership of V3 seems unlikely.

Figure 19 - The Roche lobe configurations of the V3 system. The less massive star is on the left.

6.0 SUMMARY

The Johnson V and Cousins I eclipsing light curves of Yan & Mateo (1994) have been analyzed using the University of Calgary improved Wilson-Devinney light curve modelling program and a simplex enhanced version of the same. Using the results, absolute parameters for the binaries have been calculated and the individual components have been placed on the colour magnitude diagram of Hodder *et al.* (1992). Of the five binaries, four are probable M71 cluster members based on distance determinations.

Three binaries are contact systems, but the degree of contact is not nearly so great as that demonstrated by the W UMa stars in NGC 5466 (Kallrath *et al.* 1992). This is consistent with the fact that the M71 contact systems are on or near the main sequence while the NGC 5466 systems were blue stragglers. The individual components of two of the contact systems (V1 and V5) demonstrate the common trait of having their primary components above the main sequence while their secondary components are to be found below the main sequence. This is suggestive of the more massive star having gained mass and luminosity at the expense of its companion, a result common with other W UMa systems. The contact systems have been used to test Rucinski's (1994) period-colour-luminosity relationship for W UMa stars. The results were not impressive, and imprecise colour transformations and small sample sizes are the probable cause. These systems are an important addition to the available sample of W UMa systems with derived distances and will help to refine the P-C-L relationship.

The fourth probable member, V4, is most likely a detached system although the semi-detached model was also considered since the less massive star nearly fills its Roche lobe in the detached model. A third model, the least likely based on goodness-of-fit measurements, has the hotter star more massive but smaller in size (mass ratio ~ 0.9) and

represents the occultation eclipse possibility. If the system is detached, the location of the primary component near the main sequence turn-off is potentially important for evolutionary model calibrations. The primary is notably blueward of the main sequence but the large error in (B-V) encompasses the main sequence. The theoretical evolutionary tracks of Vandenberg & Bell (1985) and the isochrones of Bergbusch & Vandenberg (1992) have been used to check for the possibility of mass exchange. Stars of masses equal to the current component masses would not have expanded past their current size and, hence, would not have exchanged mass. This fact makes V4 very similar to DS And, the components of which have similar positions on the CMD of NGC 752, and whose less massive star nearly fills its Roche lobe. The possibility of past mass exchange has also been investigated. A primordial mass ratio smaller than its current value would imply a correspondingly more massive primary star, which would be expected to have evolved faster than of the current primary star. Evolutionary tracks have been consulted and it has been concluded that past mass exchange cannot be ruled out on this basis, despite the larger size of the primordial Roche lobe required by the smaller primordial mass ratio, because of uncertainties in the cluster age and metallicity. The likelihood of mass exchange leading to a change in mass ratio to its current value of 0.38 from a smaller value has been considered. It has been argued that such a change was unlikely to occur because, once begun, mass exchange will proceed until component mass equalization was achieved. However, given the complicated nature of binary star evolution, past mass exchange cannot be definitively ruled out. The final resolution of the question V4's evolutionary status will require further information, particularly spectral information.

The fifth binary, V3, is the least likely to be a M71 member, based on its calculated distance. The resolved and combined positions of V3 on the CMD also argue against membership.

The continuing work on the Mt. Laguna 5-colour CCD images is expected to provide valuable additional information, and may help to confirm the conclusions discussed here. In particular, precise colour excess determinations will greatly reduce the uncertainty in the component positions on the CMD. B-V colour information will allow the M71 contact systems to be added to the Rucinski (1994) B-V sample and hence aid in the determination of a period-colour-luminosity relationship for W UMa stars, as can already be done for the V-I sample. The pursuit of spectroscopic information is an extremely important task to be included in future work. Radial velocity information will help in the confirmation of the membership of the M71 binaries. The large uncertainty in the total mass of the binary systems will also be addressed by the addition of radial velocity curves to the light curves analyzed here. Spectroscopic analysis will also provide better estimates for the temperatures of the stars. It may also, along with infrared observation, provide evidence for mass loss in the binary systems. This would be useful in establishing the status of the V4 binary because mass loss is an expected symptom of dynamical timescale mass transfer. Finally, spectroscopic information may provide clues concerning the composition and evolutionary state of the V4 components, which would be helpful in determining if large scale mass transfer has occurred.

* Federal Republic of Germany *

This file contains parameters which define how LCDC will work !

Explanations to the parameters

TASK : 1 = invokes computation of simple light curves

2 = invokes differential corrections

3 = invokes the simplex algorithm

4 = starts a test run - one light curve only

IWRITE 0 = no , 1 = yes ; produces lc93ks.spt

RESTRT 0 = no , 1 = yes ; requires lc93ks.spt to exists

IFSPOT 0 = use spot data from Wilson-Devinney input file

1 = use spot data from 'spot.dat'

IGRAPH 0 = no

1 = produces TopDRAWER compatible graphics after TASK=3 or TASK=4

2 = produces gnuPLOT compatible graphics after TASK=3 or TASK=4

MAXIT -1 = Shows initial simplex without evaluated vertices
 0 = Shows initial simplex with evaluated vertices
 >0 = Number of iteration to be performed

ENTRY

Never do change these four lines, because they tell the program 1
 where to find the beginning of data. 2

----- 3 ---

Specify the task (TASK = 1,2, 3 or 4) 4 TASK : 3

Would you like to write Simplex tableau to lcj.spt ? IWRITE : 1

Specify RESTART-options for simplex-algorithm [0 or 1] RESTRT : 0

Specify if you would like to produce some graphics IGRAPH : 0

Specify the source of spot data parameters IFSPOT : 1

Specify G1 G1 : 4.353

Specify G2 G2 : 4.304

***** TASK 3 *****

Maximal number of iterations MAXIT :300

Output of Simplex Tableau (YES=1,NO=0) ? IOSTYN : 1

Reflection Coefficient, >0 ALPHA : 1.00

Contraction Coefficient, $0 < \beta < 1$ BETA : 0.50

Expansion Coefficient, $1 < \gamma$ GAMMA : 2.00

Format of size parameters of initial simplex IFORM : F5.2

Format of minimal size of simplex IFORM : E6.1

Format of parameter's and SSR Output-Vector FORM1 : F9.5

Format of parameter's and SSR errors FORM2 : F9.5

Format of Data-Points FORM3 : F10.5

Divide all increments by ... INITD : 1

Specify the mode for construction of init simplex MINIT : 1

Specify stopping criteria for simplex SGMINT : 0.004
